Herpes Simplex Viruses 1 and 2

158

Gail J. Harrison • Benjamin A. Pinsky • Ann M. Arvin

Herpes simplex virus (HSV) types 1 and 2 are in the family of nine human herpesviruses, which also includes cytomegalovirus (CMV), Epstein-Barr virus (EBV), varicella-zoster virus (VZV), and human herpesviruses (HHV) types 6A, 6B, 7, and 8.

HSV-1 is the prototype of the α -herpesvirus subfamily, which includes HSV-2 and VZV.³³⁴ These viruses are ubiquitous and neurotropic and establish latency in sensory ganglia; persistence is associated with periodic reactivation and reappearance of infectious virus at mucocutaneous sites. Most individuals infected with HSV-1 and HSV-2 do not have clinical manifestations, either at the time of initial acquisition or during episodes of reactivation. When HSV-1 or HSV-2 causes disease, the illness may range from minor, such as “fever blisters,” to life threatening, as exemplified by HSV encephalitis or neonatal disease. Proper management of HSV-1 and HSV-2 infection depends on clinical recognition of the common and atypical syndromes caused by these viruses, knowledge of laboratory methods that are useful for proving the diagnosis, and early and appropriate antiviral therapy.

THE VIRUSES

HSV-1 and HSV-2 virions consist of an icosahedral protein capsid enclosing a core of double-stranded DNA, surrounded by a protein tegument, and enclosed in a lipid-containing envelope.³³⁴ The genomic DNA of HSV-1 and HSV-2 has substantial sequence homology (approximately 50%), but the viruses also have unique sequences that encode variant proteins, and they differ biologically in their patterns of replication in vitro and in vivo. Tegument proteins are located between the capsid and the viral envelope. The envelope has glycoproteins that are important targets of the humoral and cellular immune responses (gB, gC, gD, and gG). The glycoproteins gE and gI function as immunoglobulin (Ig) Fc receptors. Other glycoproteins include gH and gL, which form a complex with gB that plays a role in cell entry and spread; gK, which is required for viral exocytosis; and gM, which has a role in capsid envelopment and exocytosis. These glycoproteins are found in both HSV-1 and HSV-2 and exhibit a high degree of amino acid similarity. The gG of HSV-2 is larger than its HSV-1 homologue and has unique sites that are recognized by virus-specific host responses. Both forms of HSV can infect either oral or genital sites; however, HSV-1 usually causes infections of oral mucocutaneous sites, and most genital mucocutaneous infections are caused by HSV-2.^{123,334} HSV-1 is more likely to recur at oral sites, and HSV-2 reactivates more frequently in the genital area, even in persons who were infected initially at both oral and genital sites with HSV-1 or HSV-2.²³⁴

HSV attaches to and penetrates cells via gB and gD through specific cell surface herpes family receptors. This process also involves gH and gL. The herpes family coreceptors belong to the tumor necrosis factor family (Hve-A), the immunoglobulin superfamily of receptors (nectins), and the 3-O-sulfated heparin sulfates.³³⁴ After the virion enters the cell, an orderly expression of immediate early, or α , genes occurs that triggers viral gene transcription and inhibits host cell function; early, or β , viral genes that encode regulatory proteins and DNA replication enzymes, including thymidine kinase and viral DNA polymerase; and finally, late, or γ , genes that encode structural proteins. Replication of viral DNA and accumulation of structural proteins allow assembly of the virion capsid in the cell nucleus and envelopment by modified cellular membranes that are incorporated into the virion envelope during virion

egress. Infectious virions are released from the infected cell or can spread to adjacent cells via membrane fusion.

Human HSV replicates in tissue culture cells derived from many mammalian species and various laboratory animals, including rodents, rabbits, and primates. Lack of restriction of the host range distinguishes HSV-1 and HSV-2 from the other human herpesviruses. HSV-1 and HSV-2 replication progresses rapidly in cell culture and causes characteristic focal cytopathologic effects. Confirmation that these effects are caused by HSV can be accomplished by staining the infected cells with specific antisera or monoclonal antibodies that differentiate HSV-1 from HSV-2 and from other viral pathogens.

Like other herpesviruses, HSV-1 and HSV-2 have gene products that inhibit intrinsic cellular responses that interfere with replication and facilitate the avoidance of immune surveillance during primary infection, latency, and reactivation.⁵³ Among others, these mechanisms include elaboration of virally encoded IgG Fc receptors formed by gE/gI and complement receptors that bind host immune components; downregulation of major histocompatibility complex (MHC) class I antigen, which prevents recognition of infected cells by CD8⁺ T cells; interference with upregulation of MHC class II molecules by interferon- γ , which inhibits CD4⁺ T-cell-mediated adaptive immune responses; and inhibition of the lytic activity of natural killer cells.³³⁴

TRANSMISSION

Infectious HSV-1 and HSV-2 virions are released into the oral or genital secretions of infected but asymptomatic persons who are experiencing primary or recurrent infection. This phenomenon is referred to as viral excretion or *viral shedding* and results in periodic opportunities for the virus to be transferred to susceptible contacts. Most HSV-1 and HSV-2 transmission is caused by silent infections, and transmission occurs with equivalent frequency regardless of whether the individual who is shedding the virus has ever had symptoms of oral or genital herpes.

Although HSV-1 and HSV-2 are highly infectious after inoculation of mucocutaneous sites, they are not transmitted casually from person to person. The enveloped virions are unstable outside mammalian cells, and close interpersonal contact is required for transfer of infectious virus particles. In most circumstances, transmission requires direct apposition of infected with uninfected mucous membranes or skin during intimate contact such as kissing or sexual contact. Outbreaks associated with gingivostomatitis have occurred at daycare centers.³⁶⁵ If uninfected exposed skin or mucous membranes are damaged, the risk for transmission appears to be enhanced. Although skin is less susceptible to direct inoculation than the mucous membranes are, transmission via inoculation of skin may be increased by local trauma. For example, affected areas are more susceptible in burned patients¹⁴⁰ and infants with diaper rash. Children with eczema are at risk for contracting serious disseminated HSV infections (Kaposi varicelliform eruption).^{14,450} Transfer of HSV-1 between wrestlers (herpes gladiatorum)³⁷⁰ and between rugby players (herpes rugbeiorum or “scrum-pox”)³⁷² probably takes place after the abrasion of saliva-contaminated skin. One outbreak at a wrestling camp involved 60 of 175 participants.^{38,79} Health care workers may acquire HSV infections of the paronychia region (herpetic whitlow), presumably from direct contact of ungloved hands with oropharyngeal secretions.^{148,337} Medical personnel can transfer HSV to their patients. Children acquire HSV whitlow in the course of

primary HSV-1 gingivostomatitis through nail biting or thumb sucking. When herpetic whitlow develops in persons who are not health care workers, HSV-2 is a common cause and often is associated with primary genital HSV infection.¹⁵⁰ The usual route of transmission to neonates is by exposure during passage through an HSV-infected birth canal. Genital and anal HSV infections are transmitted through direct contact with infected genitalia or from orogenital or oroanal contact.

Newly acquired HSV-1 and HSV-2 infections are associated with shedding of high titers of infectious virus, regardless of whether the individual is symptomatic. In addition, active recurrent HSV-1 or HSV-2 lesions contain substantial titers of virus, which may increase the likelihood of transmission occurring during close contact with a susceptible individual.

The incidence of acquisition of HSV-2 is 5% to 15% per year in individuals who are HSV-1 and HSV-2 seronegative or HSV-1 seropositive but HSV-2 seronegative and whose sexual partners have recurrent genital herpes.^{272,273} In studies of discordant couples, transmission occurred in 10% of partners, with higher transmission from men (17%) than from women (4%). In women lacking antibodies to HSV-1 and HSV-2, the rate of transmission was 32%; if they had antibodies to type 1, the rate was 9%.²⁷² Studies of patients by HSV-2-specific serology show that many individuals remain uninfected despite having long-term contact with a person who is infected with HSV-2.²²⁹ The extent to which HSV-1 immunity protects against HSV-2 infection is not clear, but the evidence is that symptoms of new HSV-2 infection may be prevented if the exposed individual has HSV-1 immunity, whereas subclinical infection frequently is not blocked.^{48,62} Information about whether HSV-1 or HSV-2 acquired earlier interferes with the acquisition of infection by unrelated HSV-1 or HSV-2 strains is limited, but a few individuals with multiple sexual partners have been found to shed HSV-2 viruses that are genetically distinct.

HSV has been isolated from the hands of patients with oral lesions and has been shown to persist for several hours on inanimate objects or in distilled water. Nonetheless, inanimate sources have not been implicated as important reservoirs of HSV persistence and spread.^{291,421} HSV transmission from transplanted organs¹²⁴ and inseminated donor sperm has been reported.²⁷⁷

When HSV-1 and HSV-2 shedding has been evaluated prospectively in seropositive individuals with or without a history of symptoms, the usual frequency of detection of virus in oral or genital secretions is 1% to 2%.^{16,334} In patients with known genital herpes, silent excretion has been documented as often as 10% of the time when they appear to be lesion free. Twelve percent of women with primary HSV-1 genital infection and 18% with primary genital HSV-2 infection subsequently shed virus asymptomatically, especially in the first 3 months after resolution of the primary infection.²¹⁸ Two percent of women attending a sexually transmitted disease clinic shed HSV-2 asymptomatically.²²⁷ In partner studies, 70% of HSV-2 transmissions were associated with sexual contact during periods of asymptomatic viral shedding.²⁷³

Polymerase chain reaction (PCR) is considerably more sensitive than is culture for detection of HSV on mucosal surfaces, and the use of this technology has improved understanding of the extent of HSV viral shedding. However, it is important to recognize that the detection of segments of the viral genome by PCR does not necessarily mean that infectious virus is present. PCR detects subclinical shedding of HSV-2 on 20% to 25% of days. Factors that influence the magnitude and frequency of shedding include the site of infection, immune status of the patient, and time of acquisition of the virus.³⁴² Previous studies using viral cultures rarely reported isolation of HSV-2 from the mouth, but recent quantitative PCR studies detected asymptomatic oral HSV-2 reactivation from 40% of men with HSV-2 genital herpes. Oral HSV-2 shedding frequently is concurrent with genital HSV-2 shedding.²¹⁰

Investigation of HSV-1 transmission is less extensive, but the high prevalence of asymptomatic HSV-1 infection in the population and its acquisition in early childhood suggest a similar pattern of spread by exposure to virus present in oral secretions from asymptomatic individuals.

Both HSV-1 and HSV-2 can be transmitted to a neonate. Approximately 4% of neonatal herpes cases are acquired in utero, 86% around

the time of birth, and 10% postnatally. Three fourths of natal/postnatal cases of neonatal herpes infection are caused by HSV-2, and the remainder are caused by HSV-1 strains.²⁹⁹ Virtually all neonatal HSV-2 infections probably are acquired from mothers having an active genital herpes infection by contact with infected genital secretions at or during delivery from an asymptomatic mother who acquired her first episode of genital herpes infection in the third trimester or near the time of delivery.^{299,403,462,472} The majority of neonates with HSV appear to acquire the infection by contact with infected genital secretions at or during delivery from an asymptomatic mother who acquired her first episode of genital herpes infection in the third trimester or near the time of delivery.^{54,56,58-60} Because 60% to 80% of mothers who have newborns with HSV have no signs or symptoms of genital herpes at the time of labor and delivery and have a negative past history of genital herpes or contact with a partner who had a genital vesicular rash, some experts recommend routine serologic screening of pregnant women and their partners to identify potential at-risk mothers.^{54,56,264,454,458,459} However, based on the low accuracy of currently available serologic tests for HSV-2, and the potential harm of false-positive HSV-2 serologic tests, as well as the lack of randomized clinical trials to show that antiviral medication reduces transmission risk in asymptomatic seropositive individuals, the 2016 US Preventive Services Task Force Recommendation Statement from 2016 recommended against serologic screening for genital HSV-2 infection in asymptomatic adolescents and young adults, including those who are pregnant.^{135,424}

Neonates with HSV-1 infection can acquire the virus from several sources: maternal genital tract, oral contact with mother, breast lesions,^{54,56,59,126,254,402,474,473} oral herpes in the father or other family members,^{122,403,473,474} or health care-associated transmission from other infected infants or health care workers.^{167,255} Although HSV-1 cold sores and asymptomatic oral shedding may be common findings in nursery personnel,^{176,177} transmission to a neonate from this source appears to be rare.^{333,425} Male neonates may also contract HSV infection after out-of-hospital ritual circumcision.⁸³ In a recent report, 11 neonates were reported infected with HSV after orthodox Jewish ritual circumcision that included metzitzah b'peh, a practice in which the circumciser uses his mouth to apply direct orogenital suction to the newly circumcised penis to clean the blood away from the wound.⁸³

EPIDEMIOLOGY

Understanding HSV epidemiology requires distinguishing between the prevalence of infection, which is high, and the frequency of HSV-related disease, which is low. These viruses maintain their persistence in the human population through their capacity to persist and reactivate in the individual host. The prevalence of HSV-1 and HSV-2 is a consequence of efficient transmission to susceptible close contacts and the continuous presence of a large pool of infected persons in the population. Because HSV-1 and HSV-2 are not cleared after primary infection but instead establish latency and reactivate frequently in an infected host, opportunities for viral spread to new susceptible persons are common. Seroepidemiologic studies have shown that HSV infections are found in all human populations, even in the most remote and isolated communities. HSV-1 and HSV-2 have no seasonal pattern because the mechanism of transmission is by intimate contact, which occurs year round. Individuals who have been infected with HSV-1 or HSV-2 remain a reservoir for infectious virus throughout their lifetimes and, as intermittent shedders, are sources of virus that spreads to susceptible contacts. Most transmission is from asymptomatic infection, and most acquisition is asymptomatic. For example, the rate of subclinical shedding of HSV-2 in individuals with no reported history of genital herpes was similar to that in subjects with such a history (3.0% vs. 2.7%).⁴⁴⁰ Shedding of HSV-1 in oral secretions is equally prevalent.

When symptoms of a new HSV-1 infection do occur, the source of the infection rarely is identified because the susceptible individual usually has many infected contacts. The first symptomatic episodes of HSV-1 or HSV-2 often represent reactivations of earlier infections.

The average age at acquisition and the prevalence of HSV-1 and HSV-2 infection are influenced by the virus type. Although neonatal HSV infections are usually acquired from maternal genital infection

and usually are caused by HSV-2, HSV-1 acquisition predominates in childhood. Depending on social and economic factors, 20% to 40% of young children are seropositive by the time they reach 5 years of age, with higher rates of acquisition in lower socioeconomic groups, non-Hispanic blacks, and children born outside the United States.⁴⁷¹ Earlier acquisition of HSV-1 may be influenced by whether the mother, or other major caregivers, has HSV-1 infection. Attendance at child care centers, which brings children together in close contact, may increase the likelihood of acquiring HSV-1 at an earlier age.^{232,365} Acquisition of HSV-1 continues with age at an average rate of 1% to 2% per year throughout the childhood and adult years; by later ages, 70% to 90% of individuals have been infected by HSV-1.³⁷⁹ Seroepidemiologic studies of higher socioeconomic groups have reported HSV-1 infection in 30% to 46% of university students.¹⁴⁷

The prevalence of HSV-2 is highly variable and depends on the country, region, sex, age, population subgroup, and whether a population is “high risk.”³⁷⁶ Because transmission of HSV-2 is associated with sexual activity, the prevalence of HSV-2 begins to increase with adolescence. It is estimated that one in six individuals between ages 14 and 49 years will transmit genital HSV.⁴²⁴ Now that serologic methods can be used to differentiate HSV-1 and HSV-2 infection, the seroprevalence of HSV-2 in adults has been shown to range from 20% to 60%. Continuing comprehensive investigation of HSV-2 epidemiology in the United States by the National Health and Nutrition Examination Survey (NHANES) documented a 30% increase in prevalence from the 1970s to the 1990s, which resulted in HSV-2 infection in approximately 20% of adults in the period between 1988 and 1994.^{78,139,199} Since that time, HSV-2 seroprevalence has decreased to approximately 16% in individuals 14 to 49 years of age.⁸¹ High HSV-2 infection rates are documented in higher as well as lower socioeconomic groups, with estimated transmission occurring in one of every six individuals.^{48,227,229,401,477} Rates are consistently higher in women, non-Hispanic blacks, and individuals with multiple sexual partners. However, despite the high prevalence of seropositivity and transmission rates, serologic screening is not recommended based on the US Preventive Services Task Force Recommendation Statement because there is a high false-positive rate for HSV serologic test results, which have resulted in psychosocial harm and distress related to false-positive results. Furthermore randomized clinical trial data to support preventive antiviral treatment for seropositive individual are lacking.¹³⁵

Changes in the epidemiology of symptomatic HSV-2 infection have been suggested by rising numbers of medical visits for genital herpes. The extent to which the increase in symptomatic cases of HSV-2 infection reflects a true increase in the prevalence of HSV-2 or a higher likelihood that HSV-2 infection will result in symptoms is not certain. The decrease in the number of young adults with HSV-1 infection acquired in childhood could be associated with loss of cross-reactive HSV immunity and an increased risk for the development of symptomatic genital herpes. A higher risk for contracting genital HSV-2 infection is associated with lower socioeconomic status, early age at first intercourse, increased numbers of sexual partners, female gender, previous marriage, urban living, black race, and incidents of trichomoniasis, bacterial vaginosis, and other sexually transmitted diseases.^{139,155,198}

A retrospective analysis of genital HSV cultures obtained from a group of college students over the course of a 9-year period showed that HSV-1 is an increasingly common cause of genital herpes in some populations in the United States. In this particular population, HSV-1 accounted for more than 70% of positive genital cultures by the end of the study period, as compared with approximately 30% at the beginning.³³¹

Symptomatic disease occurs after newly acquired HSV infection at an estimated incidence of 10 to 20% or less. However, silent infections can give rise to symptoms that appear months or years later as a result of viral reactivation. The epidemiology of HSV-1 or HSV-2 reactivation as a cause of symptomatic illness depends on the prevalence of these infections in the population as a whole, but it also is influenced by host factors that perturb the balance between the virus and the infected individual. For example, HSV-related symptoms may be triggered by exposure to sunlight (ultraviolet), febrile illnesses, immunosuppression from illness or necessary therapies, and other variables. These variables

are cofactors that affect the frequency of HSV-related disease within the infected cohort but not the epidemiologic pattern of infection.

HSV infections may be transmitted from the mother to her fetus and neonate. Fulminant or disseminated primary HSV disease may occur in pregnancy, but whether it develops more often than in non-pregnant women is not clear.²³⁵ A review³⁰⁸ of seven such cases revealed (1) infection during the third trimester in all; (2) four beginning as a genital HSV infection and three as oral disease; (3) hepatitis in six, encephalitis in two, and pancreatitis in two; (4) maternal death in three (43%)—two from hepatitis and one from encephalitis; and (5) three instances of fetal death—each secondary to severe maternal systemic illness rather than direct infection with HSV. Postpartum HSV endometritis may also occur and result in disseminated infection in both mother and neonate.^{142,268}

An increased rate of spontaneous abortion occurs in women with primary genital herpes during early pregnancy, regardless of socioeconomic status.^{58,170,171,284} Premature delivery does not occur more commonly in prospectively monitored women with recurrent genital herpes,^{170,299,429,468} but most reports of neonatal herpes cases find a greater preponderance of premature infants than in the general population.^{299,462,473} This finding, however, may reflect a higher susceptibility of premature infants to HSV infection secondary to a lack of transplacentally acquired IgG neutralizing antibodies rather than being a cause of the prematurity. Recurrent genital herpes in middle-class pregnant women is no more severe or frequent than in nonpregnant ones,^{170,429,468} but older studies demonstrated more frequent and longer episodes in women of lower socioeconomic groups.^{284,292} Between 74% and 88% of middle-class pregnant women with a history of genital herpes had at least one clinical recurrence during an observed pregnancy.^{170,429,468} A mean of 2.7 to 3.0 episodes occurred during gestation, and HSV was isolated from lesions in 56% to 75% of the recurrences and in 0.6% to 12% of concomitant cervical cultures obtained during the recurrence. Asymptomatic shedding of HSV from the cervix, either between clinical recurrences or in a history-positive woman with no episodes during the observed pregnancy, was detected in 0.5% to 2.3% of the cultures obtained. Importantly, the presence of HSV shedding during the latter weeks of pregnancy was not predictive of shedding at the time of delivery.^{16,468}

The number of cases of neonatal herpes occurring in the United States each year is far less than one would expect from the probable number of pregnancies complicated by genital herpes. Of the 3.5 to 4 million annual pregnancies, 7000 to 200,000 of these women have genital herpes at some time during the pregnancy and 3500 to 14,000 have positive HSV cultures at the time of delivery.^{46,157,171,409,429,458,468} The actual number of cases of neonatal herpes per year in Seattle and Atlanta (0.1 and 0.3 per 1000 live births, respectively) would project to a national estimate of 350 to 1,050 per year in the United States.⁴⁰³ An estimate of the incidence of neonatal HSV is between 1 in 3,000 and 1 in 20,000 and may vary with the demographics and geographic location of the population. Because asymptomatic HSV infection of the neonate rarely, if ever, occurs, subclinical cases or missed diagnoses probably do not account for the differences between the estimated number of maternal and neonatal infections. More likely, neonatal infection rates in the neonates of mothers with genital herpes are far lower than currently assumed, possibly because of the preventive measures used. The estimated infection rates quoted most often currently are (1) a 33% to 50% rate for infants vaginally delivered by mothers with primary genital herpes, (2) a 3% to 5% rate for infants vaginally delivered by mothers with recurrent lesions, and (3) less than 3% for those delivered by mothers with recurrent asymptomatic shedding at the time of delivery.^{46,54,97,299,468} In the early 1970s,²⁸⁴ the following neonatal infection rates in neonates born to mothers with genital herpes during pregnancy were reported: (1) 33% in mothers with primary disease after the 32nd week of gestation, (2) 3% in mothers with recurrent episodes after 32 weeks, and (3) 42% in mothers with virus-positive lesions at the time of delivery (primary vs. recurrent episodes not specified). More recent studies have determined a significant risk for neonatal herpes occurring in neonates born to mothers with asymptomatic shedding at the time of vaginal delivery: 33% with subclinical first episodes and 0 to 3% with recurrent shedding.^{54,72-74,300,318} Accurate knowledge of the actual neonatal infection risk is important for making decisions about management (e.g., cesarean

section, prophylactic antiviral therapy). Researchers and experts have estimated that as many as 75% of neonates with HSV disease are born to mothers with no history or clinical findings suggestive of active HSV infection during pregnancy, labor, or delivery.^{5,54,72-74}

Several factors influence the risk for acquiring neonatal herpes and the severity of neonatal disease once the infection develops. The greater risk for transmitting neonatal infection by mothers with primary, as opposed to recurrent, vesicular or ulcerative lesions at the time of delivery is well established. Also, a woman with virus-positive recurrent lesions at the time of delivery is likely to be at greater risk than is a woman who is asymptomatic and shedding virus identified by HSV surveillance cultures. Other aspects of the anatomic site and the severity of maternal genital herpes also may be associated with a greater risk for development of neonatal disease: (1) maternal cervical as opposed to vulvar or buttock skin involvement—resulting in more virus being shed into vaginal secretions; (2) multiple as opposed to single vesicles or ulcers—again, more virus from multiple lesions; (3) higher titer of virus in vaginal secretions—cultures positive sooner or more intensely positive in the diagnostic virology laboratory; and (4) longer duration of fetal exposure to infected vaginal secretions because of prolonged rupture of membranes or of fetal scalp monitors.^{97,297-299}

Investigations by Yeager and associates^{473,474} indicate that no anti-HSV antibody or a low titer of such antibody in maternal and neonatal serum is associated with a greater risk for acquisition of neonatal infection and more serious disease and that high-titer antibody is associated with a lower risk. Studies of HSV antibody titers in neonates do not show an association between antibody titer and outcome of disease. More investigations are required, therefore, to determine the potential protective role of maternal transplacental anti-HSV antibody.

Premature infants have accounted for 40% to 50% of cases of neonatal herpes,^{413,454,465} in contrast to the usual prematurity rates of 6% to 18% reported in the general maternal population. Whether the increased frequency of prematurity among neonates with herpes indicates a greater propensity of mothers with genital herpes to deliver prematurely or a greater susceptibility of premature infants to HSV infection is not known. Premature infants appear more likely to have a fatal outcome.^{74,454,455}

Instrumentation of the neonate, particularly scalp electrodes for fetal monitoring, is known to increase the risk for acquiring neonatal HSV infection.^{127,207,303} Mortality rates appear to be higher in neonates with HSV-2 than in those with HSV-1 infection, probably because of the greater proportion of HSV-2-infected infants with dissemination.⁴⁵⁵ In neonatal herpes survivors, neurologic damage occurs much more frequently in infants with HSV-2 infection than in those with HSV-1 infection.^{101,455} Infants with disseminated infection (liver, lungs, adrenals), with or without central nervous system (CNS) involvement, have the highest mortality rates (70–80%); those with encephalitis have only intermediate rates (30–40%); and those with infection limited to the skin, eye, or mouth have the lowest rates (0%).⁴⁶⁵ Rarely, neonatal HSV has been implicated as a cause of sudden unexpected death in infancy.⁴⁴⁶

The prevalence of HSV infection in febrile neonates presenting to an acute pediatric emergency treatment center appears similar to that of bacterial meningitis, suggesting that HSV infection should be in the differential of neonatal fever and evaluated accordingly.⁷²⁻⁷⁴ Factors associated with neonatal HSV infection in febrile or hypothermic neonates presenting to acute care centers include history of peripartum maternal fever, history of maternal primary HSV infection, prematurity, vaginal delivery, neonatal seizures, vesicular rash, respiratory distress, thrombocytopenia, elevated hepatic enzymes, and cerebrospinal fluid (CSF) pleocytosis.⁷²⁻⁷⁴ Because the presentation of neonatal HSV is nonspecific, and delay in diagnosis and treatment is associated with significant morbidity and mortality, some experts recommend all neonates younger than 21 days of age receive evaluation for HSV infection and early empirical treatment with acyclovir.^{72-74,260}

PATHOGENESIS AND PATHOLOGY

HSV-1 and HSV-2 exhibit particular tropism for cells of ectodermal origin, including skin and neuronal cells. Initial viral replication is thought to occur at the portal of entry, usually in mucous membranes or skin. In symptomatic cases, the incubation period for primary infection

appears to vary from 2 to 20 days. In contrast to varicella, HSV viremia is difficult to detect by culture in a normal host, although it may be found in some immunocompromised patients.^{164,390} HSV DNA in plasma and peripheral blood mononuclear cells in HSV-infected neonates has been detected with PCR techniques.¹¹⁶ HSV DNA has also been detected in approximately 25% of patients with confirmed primary genital HSV infection. Women are more likely to be viremic than men, and viremia is detected more frequently early after infection.²⁰⁰

If mucocutaneous lesions are induced during primary or recurrent infection, the pathologic cell changes caused by HSV-1 or HSV-2 replication include cytoplasmic enlargement and nuclear alterations. Cell fusion may lead to the formation of multinucleated giant cells. The nuclei of infected cells often have eosinophilic intranuclear inclusions and marginated nuclear chromatin. As the cells manifest injury, a local inflammatory response ensues, intercellular edema develops, and vesicles form. The vesicles become visible as they enlarge and usually are surrounded by an erythematous margin. At later stages, the vesicles become pustular and then dry and crust. HSV lesions typically are superficial and do not scar. Vesicles that form on mucous membranes are transient, with rapid sloughing of the superficial layer, and are seen first as shallow ulcers.

HSV-1 and HSV-2 establish latency in neurons of the sensory ganglia by mechanisms that are as yet unidentified. The viruses persist in this latent state for various intervals, although frequent asymptomatic reactivation is common; reactivation induces viral replication with the production of infectious virus at mucosal or other sites. Persons who have recurrent HSV infections frequently describe tingling sensations, itching, and burning at the site of recurrence beginning several hours before the appearance of clusters of vesicles. Persons who have recurrent genital herpes may experience severe shooting pain in their legs and even urinary retention in connection with recurrence. Occasionally, recurrent HSV skin eruptions may occur in a zosteriform pattern in a distribution reflecting the sensory innervation of a particular dermatome.

Replication at the portal of entry appears to result in infection of sensory nerve endings, followed by transport of the virus to the cranial and dorsal root ganglia along neuronal axons. Latency is established regardless of whether the primary infection is symptomatic, and it appears to be an invariable consequence of HSV infection with either virus type.^{29,332,334} HSV-1 and HSV-2 persist in neuronal cells of the sensory ganglia, with substantial numbers of these cells harboring latent virus, as demonstrated by the detection of latency-associated transcripts. The latency-associated transcripts overlap the viral genes *ICPO* and *ICP34.5* in an antisense direction.^{102,334,392} The role of these transcripts in the establishment or maintenance of latency remains to be clarified.⁵³ The presence of latency-associated transcripts appears to be necessary for establishment of latency and efficient reactivation of viral production in some animal models in vivo.³¹⁰ Viral particles are not produced in latently infected cells. HSV-1 persists most predominantly in the cranial nerve ganglia, whereas HSV-2 latency occurs in the lumbosacral ganglia. Cocultivation techniques have been used to recover HSV from the dorsal root ganglia innervating the areas of skin in which persons have experienced recurrent herpes lesions. HSV-1 has been found in trigeminal ganglia, and HSV-2 has been recovered from sacral ganglia.³² Once latency is established in the sensory ganglia, antiviral drugs cannot eradicate the latent virus from infected neurons. Because the latent virus does not multiply, it is not susceptible to drugs that affect viral DNA synthesis, such as acyclovir. When reactivation is triggered, HSV-1 or HSV-2 is transported back down axons to mucocutaneous sites, where it replicates and releases infectious virus into secretions.^{29,104,332,334} Individuals with symptomatic recurrent HSV infections almost always have HSV lesions in the identical or a directly adjacent site. Reactivation is not prevented by adaptive immunity, although whether symptoms occur and whether the virus disseminates may be influenced by the host response.

The stimulus for reactivation of latent virus may be provided by iatrogenic or naturally occurring episodes of immunosuppression and by endocrine (e.g., menstruation) or exogenous (e.g., trauma, sun, acupuncture, emotional stress) factors. Ultraviolet irradiation of the usual site of recurrence of persons who have a history of recurrent oral

herpes reliably induces recurrence either quickly (within 48 hours) or 2 to 7 days later.³⁸⁰ Skin subject to recurrent HSV infection has been transplanted elsewhere on the body and exchanged with skin taken from the site of graft placement and previously not involved in HSV infections. Subsequent recurrence of HSV infection was found to be localized to the original site, not to the original skin. These studies and others strongly suggest that latent virus does not reside in skin cells.

Primary HSV infection elicits humoral and cellular immunity, which can be detected shortly after the appearance of lesions in individuals in whom symptoms develop. Based on animal models and some human studies, the initial host response is mediated by innate, nonspecific mechanisms, followed by the acquisition of virus-specific adaptive immunity.²¹⁹ The nonspecific response consists of mobilization of polymorphonuclear leukocytes and monocytes to the site of infection, release of interferon- γ and other cytokines, and activation of macrophages and natural killer cells. The innate response is followed by the production of antiviral antibodies that can be detected 2 to 12 weeks after infection occurs. HSV-specific antibodies mediate neutralization of virus, complement fixation, and cellular or complement cytotoxicity. Induction of specific cellular immunity is detected by measuring T-cell recognition of HSV proteins in proliferation and cytotoxicity assays and production of interleukin-2 and interferon- γ . Failure of virus-specific, cell-mediated immunity to develop, as may occur in neonates and children with genetic immunodeficiencies, immunocompromised children, and other high-risk populations, can be associated with life-threatening dissemination of HSV-1 or HSV-2. Disseminated HSV can infect and destroy cells in many organs (e.g., the lungs, liver, adrenals, and brain), with multiple-organ hyperinflammation leading to massive apoptosis, with catastrophic effects. It is likely that disseminated HSV in the neonate and in the older child and adult causes a systemic inflammatory response syndrome that often leads to a fatal outcome. One case report reported the sequential changes of hyperinflammation in a neonate with disseminated HSV disease. As the HSV DNA copies rose in the patient's serum, an increase in the biomarker concentrations of first high-mobility group box 1 and then cytochrome c was observed. Antiinflammatory interventions with prednisolone, high-dose immunoglobulin, blood exchange, and high-dose acyclovir were used for treatment, and the patient survived.²⁸² A small group of immune-seronegative individuals with HSV-specific T-cell responses has been described. None of these individuals had clinical symptoms of oral or genital HSV. All had exposure to HSV-2-positive sexual partners, but HSV was never isolated by culture or PCR assay from these exposed individuals, even after extensive sampling over a prolonged period.³¹⁶ Studies are in progress to determine whether genetic immunologic determinants of disease or mutations in HSV entry receptors alter susceptibility to HSV infection.³⁹⁸

Symptomatic HSV-1 and HSV-2 recurrences are less severe than are primary lesions in immunologically intact persons. In persons previously infected with one type of virus (e.g., HSV-1), new infections with the second type (e.g., HSV-2) more often are silent, or the symptoms are less severe than in a host who has never been infected with either virus. When reinfection with unrelated strains has been identified, symptoms also have been mild and, without molecular analysis of viral DNA, would be attributed to reactivation of endogenous virus.⁶⁵ The immune response to symptomatic reactivation is not associated with a significant increase in the production of antibody, although fourfold rises and reemergence of IgA and IgM antiviral antibody may occur. Natural killer cell activity and cytokine production increase. Relative defects in these and HSV-specific T-cell responses may predispose the individual to frequent or severe symptomatic recurrences. A cohort of patients with severe eczema, sinopulmonary infections, elevated serum IgE levels, eosinophilia, and cutaneous viral infection (including severe HSV) caused by DOCK8 deficiency has been described.⁴⁷⁶ Patients who have diseases or are being treated with agents that reduce cell-mediated immunity, such as those undergoing antitumor chemotherapy or individuals with acquired immunodeficiency syndrome (AIDS), often have frequent HSV recurrences that are longer in duration and more severe, but dissemination rarely occurs.

Viral encephalitis is the most severe consequence of HSV infection in an otherwise healthy host. HSV-1 is the pathogen in almost all these cases, and the pathologic mechanism is thought to be ascending infection

along neuronal pathways from the cranial nerve ganglia to the brain.¹⁰⁹ Encephalitis may accompany or develop after primary HSV infection, but it also occurs as a consequence of reactivation of latent virus. When the virus reaches brain parenchymal cells, it replicates efficiently and induces widespread hemorrhagic necrosis and vascular compromise. The neuroimmune response to infection contributes to brain inflammation and subsequent sequelae. Activated glial cells (astrocytes and microglia) respond to HSV infection with the production of cytokines and chemokines.²⁵⁹ HSV encephalitis has been associated with an acute-phase elevation in β_2 -microglobulin, neopterin, interleukin-6, and interferon- γ in CSF.^{22,23} During convalescence, increased levels of soluble CD8, β -microglobulin, neopterin, and specific anti-HSV IgG have been detected. How these markers relate to the pathogenesis of disease has not been established.

Genetic heterogeneity involving a collection of inborn errors of immunity to HSV may predispose to herpes encephalitis. To date, signal transducer and activator of transcription-1 (STAT1), UNC93B, Toll-like receptor-3 (TLR3), and TNF receptor-associated factor-3 (TRAF3) deficiencies and nuclear factor- κ B (NF- κ B) essential modulator mutations have been found in a few children with herpes encephalitis.^{21,70,477} Most recently, TIR-domain-containing adapter-inducing interferon- β (TRIF) deficiency has been reported in children with herpes encephalitis, demonstrating the importance of TRIF for the TLR3-dependent production of antiviral interferons in the CNS during primary infection with HSV-1 in childhood.³⁵² A recent genetic epidemiology survey suggests that childhood HSV encephalitis, although sporadic, may result from mendelian predisposition (from autosomal recessive susceptibility in particular), at least in some children.¹

HSV may be transmitted to the neonate in utero either by a transplacental (congenital infection) or ascending route, at the time of birth (natal infection), or after birth (postnatal infection).⁴¹³ Congenital infection probably results from transplacental transmission of virus secondary to leukocyte-associated viremia in a mother with genital herpes, but no direct evidence supports this hypothesis. HSV-2 viremia has been documented in two women with primary genital herpes.²⁰¹ A report of 13 neonates with intrauterine HSV infection indicated that primary genital herpes was present during pregnancy in four mothers, recurrent disease was present in one, and no history of genital herpes was elicited in the remaining eight.³⁷⁵ In the fetus, HSV appears to be transmitted directly from the placenta through the bloodstream to target organs. Because of the known tropism of HSV for the CNS, one is not surprised that most infants with congenital infection have evidence of brain involvement at birth.³⁷⁵ Intrauterine infection also may occur by an ascending route from an infected maternal genital tract, and such transmission is supported by the development of clinical signs of HSV infection in the first 5 days of life.

The natal infection presumably is acquired secondary to aspiration of infected vaginal secretions into the nares, oropharyngeal cavity, conjunctivae, and upper respiratory tract of the infant. Other portals of entry for natal infection include the scalp, skin, and umbilical cord. In postnatal HSV infection, no evidence supports the genital tract as a source of virus. Most postnatally acquired infections appear to result from contact with saliva from persons with oral herpes or with virus carried on the hands of personnel. After natal or postnatal acquisition of HSV occurs, initial replication of the virus occurs at the portal of entry, which most often may be the conjunctivae or oral mucosa, with subsequent viremic dissemination to viscera. Involvement of the CNS occurs either from hematogenous spread to the brain in infants with disseminated disease, which results in meningoencephalitis and multiple areas of cortical hemorrhagic necrosis, or from retrograde axonal transport of the virus to the CNS from localized, superficial replication in the skin, eye, or mouth.

CLINICAL MANIFESTATIONS

Most HSV-1 and HSV-2 infections do not cause symptoms, but when infection is symptomatic the clinical manifestations usually are self-limited and not severe. If symptoms occur, the disease associated with primary infection tends to be much more extensive than are the minor, localized lesions at mucocutaneous junctions caused by viral reactivation.

Nonetheless, prospective studies document that new HSV infections can be as mild as symptomatic recurrences, and, as a result, definitive differentiation of primary from recurrent infection is not possible with clinical criteria.

Gingivostomatitis

Gingivostomatitis is the most common form of HSV-induced primary illness in children. A history of such symptoms has been reported in as few as 1% to as many as 31% of seropositive children, the higher percentage being from a study involving the Navajo Indians. It usually is seen in young children between 10 months and 3 years of age. In those younger than 10 months old, residual maternal antibody probably modifies or prevents the appearance of recognizable symptoms in association with primary HSV-1 infection. Although acute gingivostomatitis caused by HSV is a relatively infrequent occurrence, it is sufficiently common that most pediatricians are familiar with the condition and learn to distinguish this infection from herpangina.^{302,334}

The illness begins with irritability and fever. Despite these systemic symptoms, HSV is not cultured from blood during this period¹⁶⁴; however, investigators have detected HSV-1 DNA by PCR assay in whole blood or plasma early in the course of illness in approximately a third of young children with primary HSV-1 gingivostomatitis.¹⁶⁹ The infant usually refuses to eat and may refuse fluids. Thereafter, vesicular lesions appear around and on the lips, along the gingiva, on the anterior tongue, and on the anterior (hard) portion of the palate (Figs. 158.1 and 158.2).

FIG. 158.1 Primary herpes simplex virus gingivostomatitis in a normal toddler: ulcerative-vesicular stage. (Courtesy Dr. Theodore Rosen, Department of Dermatology, Baylor College of Medicine, Houston.)

FIG. 158.2 Primary herpes simplex virus gingivostomatitis with ulcers of the oral mucosa in a 6-year-old child.

The vesicles break down rapidly, and, when seen, lesions usually appear as 1- to 3-mm shallow gray ulcers on an erythematous base. The gums are erythematous, mildly swollen, and ulcerated. They may appear friable and bleed on contact. The child experiences extreme discomfort, will not eat, and, if fluids are refused as well, may require hospitalization to ensure that adequate hydration is maintained. The risk for dehydration is compounded by the fever that generally accompanies this syndrome. Vesicles often extend around the lips and chin or down the neck in an immunologically intact child. The child frequently has foul-smelling breath (fetor oris). The lesions bleed easily and may become covered with a black crust. The cervical and submental nodes usually are swollen and tender. The clinical signs continue to evolve for 4 to 5 days, and the process of resolution requires at least an additional week. In an analysis of the natural history of HSV gingivostomatitis in 36 children, oral lesions persisted for an average of 12 days, most children had extraoral lesions, fever lasted for 2 to 6 days, and difficulty taking liquids was noted for 4 to 10 days. The duration of viral shedding was 7 days (range, 2 to 12 days).⁷ Herpetic epiglottitis⁴⁷ and acute otitis media⁸⁹ and severe hepatitis⁸⁸ are unusual complications. In addition, transverse myelitis and severe acute disseminated encephalomyelitis have occurred after herpetic gingivostomatitis.³⁵⁵

HSV gingivostomatitis is differentiated from herpangina, a manifestation of enteroviral infection, by the location of ulcers in the anterior portion of the oropharynx. Herpangina generally causes posterior pharyngeal ulcers. In addition, unlike HSV infection, herpangina often has a more acute onset, a shorter duration, and seasonal occurrence.³⁰² Whereas enterovirus-associated hand, foot, and mouth disease can manifest as oral ulcers and a vesicular eruption on the distal portions of extremities, its bilateral distribution should differentiate it from HSV gingivostomatitis and concurrent HSV autoinoculation of a digit. Severe Stevens-Johnson syndrome (erythema multiforme) may mimic HSV infection, but the generalized macular rash accompanied by bull's-eye lesions is characteristic of erythema multiforme. Rarely, recurrent HSV infection can be associated with erythema multiforme (see later discussion). Impetigo may be confused with the lesions of HSV infection, and misdiagnosis is reinforced because colonization of skin by *Staphylococcus aureus* may be identified in bacterial cultures and be considered causative.

Parents and caregivers are familiar with “cold sores” or “fever blisters” but may not know that these lesions are caused by HSV. Because HSV infection may be thought of as a sexually transmitted disease, the physician is advised to anticipate confusion and anxiety when making the diagnosis of HSV oral infection and to address these concerns by explaining the normal mode of acquisition of oral HSV infection by young children.

Pharyngitis, Tonsillitis, Epiglottitis, Supraglottitis, Laryngotracheitis

In adolescents, primary HSV-1 infection can be seen initially as ulcerative, exudative tonsillopharyngitis.²⁷⁰ Characteristic findings are shallow tonsillar ulcers with a gray exudate. HSV infection of the tonsils may be HSV type 1 or 2 and must be differentiated from streptococcal and Epstein-Barr virus infection and rarely from diphtheria, acute human immunodeficiency virus (HIV) infection, and tularemia-induced pharyngitis. In one study of college students of a higher socioeconomic level, HSV was the most common etiologic agent of acute pharyngitis (24%).¹⁴⁹ Another study of 613 college students with upper respiratory tract complaints documented an incidence of 5.7% with positive HSV cultures. Twelve of the 35 students with positive cultures had vesicular lesions on their lips, throat, or gums, and 29 of the 35 had a primary diagnosis of pharyngitis that was indistinguishable from other causes of pharyngitis.²⁷⁰ In some cases, acute pharyngitis is caused by HSV-2; the symptoms and clinical course appear to be similar to HSV-1, but also may be severe, and viral cultures or PCR tests are required to identify the type of infecting virus.³³⁶

Acute, prolonged, atypical laryngotracheitis or herpetic croup, often nonresponsive to steroids, also may be caused by HSV types 1 or 2, in both normal and immunocompromised patients of all ages.⁸⁶ The diagnosis can be made by laryngoscopy with appropriate viral HSV culture and PCR studies and tissue immunohistochemistry for HSV antigens.

FIG. 158.3 Course of primary and recurrent herpes simplex virus (HSV) genital infection. The days illustrated are for average cases.

Epiglottitis, now a relatively rare disease in children, may rarely be caused by HSV in neonates, as well as older children, and should be included in the differential diagnosis of causes of epiglottitis, in addition to the usual *Haemophilus influenzae* and *Staphylococcus aureus* bacterial causes.²⁶³

Vulvovaginitis, Genital Herpes Infections

Primary herpetic vulvovaginitis occurs rarely in infants and children. HSV-1 may cause this clinical syndrome, perhaps if inadvertently introduced when the genital area is touched by a caregiver with HSV on the hands. Progression of the infection may be limited to a few lesions, or it may resemble symptomatic primary genital herpes caused by HSV-2. Obtaining material for culture to identify the type of infecting virus is important because HSV-1 infection is less likely to recur and HSV-2 infection may reflect sexual abuse of the child. Genital HSV infection in young children warrants a careful and sensitive appraisal of the circumstances that possibly led to the infection. Children infected with HSV-2 in the neonatal period have had genital lesions later in childhood.

Pediatricians are likely to encounter genital herpes in their adolescent patients.¹⁹⁰ Reports on the incidence of genital herpes in which data are provided for subgroups of children and adolescents are limited, but a rate of three per 100,000 in the 10- to 14-year-old age group and 76 per 100,000 in the 15- to 19-year-old age group was reported in a Minnesota study of a predominantly white, middle-class population of northern European ethnicity.⁹⁰ Older NHANES studies reported the prevalence in 12- to 19-year-old subjects to be 5.6%.¹³⁹ Recent NHANES data (2005 to 2008) show a decrease in HSV-2 seroprevalence in this age group, most recently to 1.4% in 14- to 19-year olds.⁴⁷² In one report of 379 adolescents aged 14 to 19 years who were treated at a sexually transmitted disease or urban community clinic, 12% had HSV-2 antibodies and only 22% of these patients had a history of genital herpes. HSV-2 seropositivity correlated with black race or female gender but not with condom use, the number of sexual partners in the previous 2 months, or a previous history of a sexually transmitted disease, thus indicating that prevalence was related to demographic rather than behavioral variables.³⁹⁹

Prospective studies have documented that many infections are subclinical and that new genital HSV-2 infections have a wide range of manifestations.^{242,273} Variation is common with respect to the extent and severity of lesions; whether the lesions are bilateral or localized; the presence or absence of systemic symptoms such as malaise, myalgia, headache, and fever; dysuria; and regional lymphadenopathy. Symptoms can be mild enough to suggest recurrent infection or may be those of

FIG. 158.4 Primary genital herpes in a female. (Courtesy Dr. Theodore Rosen, Department of Dermatology, Baylor College of Medicine, Houston.)

severe, “classic” primary genital herpes. In such cases in adults, local genital symptoms include severe pain (in 95% of men and 99% of women), itching, dysuria (44% of men and 83% of women), vaginal or urethral discharge, and tender inguinal adenopathy (80%). The lesions begin as vesicles or pustules and progress to wet ulcers and then to healing ulcers with or without crusts (Figs. 158.3 to 158.5). Crusting usually occurs only on squamous epithelium. Lesions tend to last for 2 to 3 weeks (mean, 19 days) before complete healing occurs. They may spread in a wavelike fashion from the initial site to the thighs, buttocks,

FIG. 158.5 Primary genital HSV infection in a male. (Courtesy Dr. Theodore Rosen, Department of Dermatology, Baylor College of Medicine, Houston.)

and urethra. Virus shedding generally persists for 1 to 2 weeks or longer. Some primary infections are associated with atypical lesions (e.g., fissures, furuncles, excoriations), and extragenital lesions, typically on the buttocks, may be observed.^{40,227}

When evaluating potential primary genital herpes in a sexually active adolescent, the history may reveal recent contact with a partner who is known to have recurrent genital herpes. When exposure can be documented, the incubation period is estimated to be 2 to 14 days. However, most episodes will not be associated with a known exposure. It is important to recognize that as many as two thirds of first-reported episodes of symptomatic genital herpes actually are caused by reactivation. The exposure may have occurred months or years before the signs of HSV-2 infection appear. In some adult series, 50% to 60% of persons without a history of HSV infection can identify symptoms consistent with previous infection after receiving education about the typical signs, but many have not had any previous episodes.²⁴⁰ HSV-1 accounts for 5% to 25% of primary genital HSV infections in the United States. Up to 50% of cases diagnosed in other geographic areas, such as England and Japan, are caused by HSV-1. Indications are that HSV-1 is becoming a more common primary genital isolate in the United States. In recent years, HSV-1 has been isolated from genital cultures more often than HSV-2 has in some populations.³³¹ Patients with primary HSV-1 genital infection occasionally exhibit lesions elsewhere (25%), typically on the hands and face.⁴⁰

Primary genital HSV-2 infections may be associated with viral meningitis. It also may be associated with recurrent aseptic lymphocytic meningitis, or Mollaret meningitis.^{286,317} This complication is manifested as fever, stiff neck, headache, and photophobia with a CSF lymphocytic cellular response and usually a normal glucose level.^{180,411} HSV-2 can be isolated in cell culture or detected by PCR from CSF obtained in

the early phase of the illness. HSV-2-associated meningitis differs from HSV-1 encephalitis in that it is almost always mild, self-limited, and not associated with neurologic sequelae.

Other complications of primary HSV genital infection include sacral autonomic nervous dysfunction, which is manifested as poor rectal sphincter tone, constipation, sacral anesthesia, urinary retention, or impotence. Extragenital lesions may be present. These are more frequent in women and occur on the buttocks, groin, thighs, or, less commonly, the fingers or conjunctiva, generally in the second week of disease. In addition, secondary yeast infections in women, and pharyngitis, which usually is associated with fever, malaise, myalgia, headache, tender anterior cervical adenopathy, and a mildly erythematous to diffusely ulcerative or exudative posterior pharyngitis may be seen. Most patients have throat cultures positive for HSV. HSV has been associated uncommonly with acute salpingitis²⁴⁹ and inguinal lymphadenitis.⁴⁰⁷ Transmission to the fetus or neonate is an important and very serious complication of primary or recurrent genital herpes in women of child-bearing age.

Of critical importance is the association of previous HSV infection with an increased incidence of HIV infection.³⁸⁸ Investigators have considered the possibility that the risk for infection with HIV is enhanced by mucosal ulcers or that the increase in local CD4⁺ lymphocytes resulting from HSV infection offers a greater number of target cells for HIV attachment and entry. Conversely, individuals with HIV infection reactivate HSV frequently and also have HIV present in mucosal ulcers.⁴³⁷ A study from Kenya showed that HSV shedding was associated with significantly higher vaginal and cervical HIV shedding, even after controlling for plasma HIV load and CD4⁺ count.²⁸ Although all patients with HSV-2 genital infection appear to be at higher risk for acquiring HIV infection, those with recent HSV-2 seroconversion appear to be more susceptible.^{329,415} This finding has been confirmed in other populations.²⁰⁶

Genital herpes creates significant psychological difficulties for many patients. Whereas many people cope well with the illness and the likelihood of recurrent disease, a syndrome of profound depression, poor self-esteem, complete abstinence from sexual activities, and general withdrawal develops in some. This reaction, or “leper syndrome,” must be anticipated and discussed in a sensitive and caring manner. Information about the high prevalence of these infections in the population may be helpful, with emphasis placed on the fact that most infected people do not realize that they are infected and shed the virus intermittently, just like those who have had symptoms, as well as effective treatment options.

Primary Herpetic Skin Infections

Mucocutaneous junction areas are common sites of HSV infection, and damaged skin often provides a portal of entry for HSV. Vesicular lesions spread throughout the affected skin and usually crust and resolve in approximately 1 week. The illness accompanying eczema herpeticum can be severe (Fig. 158.6) and even fatal, and this condition is often referred to as Kaposi varicelliform eruption. Predisposing skin conditions such as epidermolysis bullosa also may predispose infants and children to severe skin super infections with HSV and Kaposi varicelliform eruption.¹⁸⁶ However, most cases of uncomplicated eczema herpeticum in otherwise healthy children resolve and leave no sequelae. Increased use of topical calcineurin inhibitors has raised concern regarding possible immune suppression and an increase in cases of eczema herpeticum. One study showed the incidence density of herpesvirus skin infections to be similar in infants who received 1% pimecrolimus cream and those who received the vehicle without active drug.³⁰⁴ However, of those children characterized as having eczema herpeticum (more extensive skin involvement), all infants were in the group receiving 1% pimecrolimus cream. Further studies are needed to determine the magnitude of risk, if any, of the use of topical calcineurin inhibitors in the development of eczema herpeticum. Current recommendations include discontinuing topical calcineurin inhibitor therapy and beginning appropriate antiviral therapy expeditiously if eczema herpeticum develops.³⁰⁴ Topical steroids may also predispose to eczema herpeticum.

Widespread herpetic lesions may occur in skin altered by thermal or chemical burns. In this situation, a secondary fever may occur, usually 1 week to several weeks after the initial insult. Careful inspection of

FIG. 158.6 Extensive herpes simplex virus infection in an infant with atopic eczema (Kaposi varicelliform eruption). (Courtesy Dr. Theodore Rosen, Department of Dermatology, Baylor College of Medicine, Houston.)

FIG. 158.7 Secondary herpes simplex virus infection at a burn site in a 2-year-old child. Note the vesicles at the border of the burn.

the burn site or adjacent normal tissue may reveal vesicles (Fig. 158.7) or nonspecific ulcerative lesions. Without therapy, these patients may die of disseminated HSV infection.¹⁴⁰ A similar syndrome occurs rarely in children after they have incurred simple skin abrasions (Fig. 158.8). Herpetic recurrences may follow in these cases, but recurrences are localized to the area of skin that was affected initially. HSV can even cause minor or severe infection at the site of common diaper rash.¹⁹⁵

Herpetic whitlow is a painful, erythematous, swollen lesion that occurs on the terminal phalanx, sometimes associated with a damaged cuticle.^{36,134,148,337} The fingers (69%) and thumb (21%) are involved most frequently.¹⁴⁸ Less commonly, the palm may be the site of inoculation and major involvement.³⁵⁹ The digit is swollen, and the painful white swelling appears to be filled with pus but, when opened for drainage, is found to contain little fluid and no purulent material. The white appearance is caused by the presence of necrotic epithelial cells. Occasionally, the whitlow, which may persist for 7 to 10 days, is accompanied initially by a few vesicles that may give a clue to the etiologic agent of the primary infection. Less commonly, the whitlow is associated with fever, lymphadenopathy, and lymphangitis.³⁵³

FIG. 158.8 Facial herpes simplex virus infection in a young girl after a mild abrasion. (Courtesy Dr. Johnie Frazier, Department of Pediatrics, University of Texas Medical School, Houston.)

FIG. 158.9 Extensive herpetic whitlow in a toddler with oral herpes simplex virus infection.

Whitlow is seen in four typical situations.¹³⁴ Most commonly, infants with primary herpetic gingivostomatitis autoinoculate their fingers (Fig. 158.9). At times, whitlow is encountered in infants without obvious oral disease, and sometimes it may be caused by adults kissing their children's fingers. In these settings, the viral isolate almost always is HSV-1.^{36,148} In sexually active patients, the whitlow more commonly is a manifestation of concurrent genital disease, which should be sought by appropriate history and physical examination.¹⁵⁰ These infections are caused most frequently by HSV-2. In the fourth setting, persons such as dentists, respiratory therapists, nurses, and pediatricians who examine oral cavities or handle secretion-contaminated material without wearing gloves are at risk for acquiring herpetic whitlow (Fig. 158.10).¹³⁴ In addition, health care-associated transmission of HSV to other patients, especially in intensive care settings, may occur if careful attention to use of gloves and other personal protective equipment is not practiced.³

FIG. 158.10 Recurrent herpetic whitlow in a pediatrician.

Herpetic whitlow frequently is confused with bacterial felon, paronychia, or osteomyelitis of the fingertip. Such confusion may lead to the incorrect intervention of incision and drainage. This procedure is not indicated and is not beneficial in the management of herpetic whitlow, which should be treated with oral acyclovir. Needle aspiration and bacterial and viral cultures provide the diagnosis of whitlow, and initiation of antiviral therapy can be based on clinical signs.

In several sports, cutaneous (especially facial) HSV infection is a hazard, particularly in sports with close physical contact such as wrestling (herpes gladiatorum) and rugby (scrum pox, a name derived from the lineup of rugby players, the “scrum” or “scrummage”).^{38,79,370,372,451} Frequently, the initial lesions are misdiagnosed as impetigo. HSV infection develops in approximately 3% of wrestlers in high school, typically on the head and neck but also on the extremities and trunk and in the eyes.⁷⁹

Infection of the Eye

Ocular herpes occurs as a result of primary infection or reactivation of virus in the trigeminal ganglion. Primary infection may manifest as blepharitis or follicular conjunctivitis. The symptoms often are accompanied by preauricular lymphadenopathy, corneal injection, watering, discharge, itching, lid swelling, and, in a third of cases, malaise and fever. If the infection is restricted to the conjunctivae (which can be accompanied by vesicular herpetic lesions elsewhere on the face or in the nose or mouth), it usually resolves without sequelae or specific features. Herpetic infection of the eye may progress to involve the cornea and progress to keratoconjunctivitis, with far more serious potential consequences. Neonatal HSV infection may also present as keratoconjunctivitis and has been reported after cesarean section delivery over intact chorioamniotic membranes and in twin deliveries.^{145,442} For this reason, an ophthalmologic consultant always should examine and evaluate these cases.

Corneal involvement by HSV may be manifested initially as minute vesicles at the corneal margin. Progression of the corneal infection (best seen with the use of topical fluorescein dye) is marked by the appearance of branching lesions (a dendritic pattern) or the less diagnostic irregular (ameboid or geographic) ulcer.^{37,106} The child complains of severe photophobia often accompanied by blurred vision, chemosis, and lacrimation. Primary eye infection may include stromal involvement, uveitis, and, rarely, retinitis.³⁰⁵ Retinitis is manifested as multiple whitish yellow, punctate retinal lesions. Spontaneous healing, which generally requires 2 to 3 weeks, can be speeded by the application of topical antiviral therapy. Corticosteroids are contraindicated. The risk for visual impairment caused by direct viral damage, immunopathologic reactions, or both is enhanced greatly with recurrences. With each bout of infection, the corneal ulcers become more extensive and can result in scarring and impairment of sight. Herpetic infection of the eye recurs in approximately 32% of patients who have primary symptomatic infection and occurs more commonly in younger patients.⁴⁶⁷ Recurrences may be manifested as blepharitis, follicular conjunctivitis with or without lid lesions, or ulcers and keratitis, which more often are accompanied by ulcerations deeper into the corneal stroma (diskiform or necrotizing keratitis) with resultant extensive scarring, irregular astigmatism, and

even corneal perforation.⁴⁶⁷ Children with dendritic ulcers have a better prognosis for good vision than do those with geographic or diskiform keratitis.³⁷

Rarely, HSV eye infection results in acute retinal necrosis. HSV-2 is the most common cause of acute retinal necrosis identified in childhood. Most affected children have a history of congenital or perinatal herpes infection.²³⁹ Acute retinal necrosis may also be a late sequela of HSV-1 encephalitis.¹⁰⁵ Many patients have preexisting chorioretinal scars. Reactivation is triggered by periocular trauma or occurs with immunosuppression, such as during treatment with systemic corticosteroids.⁴¹⁷ Symptoms include eye irritation and photophobia.

Very infrequently, an oculoglandular syndrome of conjunctivitis and preauricular adenopathy may be caused by HSV infection.⁶⁹

Infections of the Central Nervous System

HSV is the most common identifiable cause of serious or life-threatening sporadic, endemic encephalitis.²⁵² It accounts for 2% to 5% of all cases of encephalitis in the United States and for as many as 20% of all cases with an etiologic diagnosis (60–70% of cases of encephalitis have no established cause).³²⁵ With the advent of immunization for measles, mumps, rubella, and varicella, the relative incidence of HSV in cases of encephalitis has increased, although absolute numbers remain stable in children.^{224,252,325} The case-fatality rate associated with untreated HSV encephalitis is approximately 70%,⁴⁶⁴ and survivors generally have severe and permanent neurologic disability. Both HSV-1 and HSV-2 have been implicated in the etiology of CNS infection by HSV, but typical HSV encephalitis in patients outside the neonatal age range is caused by HSV-1.^{1,102,334,358} Spread of HSV-1 to the CNS seems to proceed either via neurogenic pathways or by hematogenous dissemination, or perhaps through the cribriform plate from infected nasopharyngeal mucosa during primary infection. Recurrent infection probably results from spread via sensory neurons. HSV-2 meningitis is not associated with brain parenchymal infection; whether the infection is a consequence of hematogenous delivery or spread along neuronal pathways is not known.

Although HSV encephalitis may involve virtually any area of the brain, or even the entire brain and spinal cord, this infection has a striking tendency to involve the orbital region of the frontal lobes and, with particular frequency, portions of the temporal lobes. The predilection of HSV to involve regions of the brain governing olfaction suggests that a pathogenetic pathway proceeds from the nasal-respiratory mucosa via the olfactory bulbs and along the subsequent tracts into the brain.¹⁹⁸ Other researchers have suggested that reactivated virus travels from the trigeminal ganglia via fifth nerve fibers to the meninges of the anterior and middle fossae.^{109,110} HSV brain stem encephalitis also occurs and may be associated with neuroophthalmologic findings and cranial nerve deficits.³⁰⁹ Studies in children involving diagnosis by PCR assay and magnetic resonance imaging (MRI) have defined cases with more diffuse cerebral involvement.^{334,360,430}

HSV encephalitis must be differentiated from primary or recurrent HSV meningitis (Mollaret meningitis), which usually is caused by HSV-2 and is a complication of primary genital or oropharyngeal infection. In HSV meningitis, symptoms and signs of meningitis, including headache, photophobia, and stiff neck, appear before or shortly after genital or oropharyngeal lesions are noted. The signs are similar to those of other acute viral meningitides such as enteroviral meningitis. This syndrome may occur in children and adolescents as well as in adults.¹¹⁹ HSV-2 meningitis is reported in the absence of lesions³⁶² and rarely in neonates.³⁶¹ Seizures and focal CNS findings generally are absent. Examination of CSF reveals lymphocytosis (with 300 to 2600 white blood cells) and may demonstrate low glucose levels. In cases of HSV meningitis, in contrast to HSV encephalitis, virus is often cultured from CSF,^{16,18,102,180} and HSV PCR assay also is diagnostic.³⁶² Recovery usually is complete without specific therapy, but with the availability of effective antiviral agents, HSV meningitis should be treated with acyclovir. HSV meningitis may reappear with or without obvious genital recurrences. Studies using PCR DNA detection analysis have shown that HSV is the major agent responsible for benign recurrent lymphocytic meningitis.⁴⁰⁸ These adult patients had three to nine attacks of recurrent lymphocytic meningitis, with 48 to 1600 cells/L, normal glucose, and

TABLE 158.1 Historical and Clinical Findings in Herpes Simplex Virus Encephalitis

protein concentrations of 41 to 240 mg/dL in CSF. PCR analysis detected HSV-2 and, less commonly, HSV-1. Acute viral meningitis caused by reactivation of HSV-1 also has been described in a preadolescent child.⁹⁶

HSV encephalitis is a highly lethal disease caused by HSV-1 in 93% to 96% of cases.^{25,285,334,452,456} It may be a result of primary (30%) or recurrent (70%) infection.^{285,334} Although no specific data exist, researchers have suggested that HSV encephalitis is more likely to be associated with primary infection in younger persons because new infections occur more commonly in this age group. One report suggests that primary infection is more likely to be associated with fatal encephalitis. Of 113 cases of biopsy-documented HSV encephalitis, 31% occurred in patients younger than 20 years, and 6% to 10% of patients were between 6 months and 10 years of age.^{374,375} Unlike most other common forms of viral meningoencephalitis such as enterovirus or arbovirus infection, HSV encephalitis is not seasonal. It is an acute illness characterized by fever, headache, malaise, irritability, and nonspecific symptoms lasting 1 to 7 days, with progression to the signs and symptoms of CNS involvement in 3 to 7 days and, finally, to coma and death (Table 158.1). A biphasic illness consisting of initial improvement followed by worsening may occur. The signs of HSV encephalitis resemble those of other viral encephalitides, with initial fever and altered behavior.¹⁷² Meningeal signs are uncommon findings. No correlation exists between isolation of HSV from sites extrinsic to the CNS (e.g., the oropharynx or genital tract) and the diagnosis of HSV encephalitis.^{285,453} Thus, the presence of oral or genital lesions is of no help in establishing or excluding the diagnosis of HSV encephalitis. Nonetheless, if a patient has HSV encephalitis, identical viruses have been isolated from the brain and oral secretions.⁴⁶⁰ Herpes simplex encephalitis has also been reported as a rare complication of neurosurgical procedures, craniotomy, and stereotactic radiotherapy.¹⁹³

The CSF in herpes encephalitis generally reveals pleocytosis, usually (80% of the time) more than 50 white blood cells/mm³, with as many as 2000 white blood cells/mm³ in some cases. In 90% of cases, more than 60% of the cells are lymphocytes. Early in the course of infection, neutrophils may predominate and there will be few or no red cells. In advanced cases, red blood cells, reflecting the hemorrhagic necrosis, may be seen in the CSF. Between 5% and 25% of patients have hypoglycorrhachia, and 80% to 88% have elevated protein levels in CSF (median, 80 mg/dL), which rise to striking levels as the disease progresses if untreated. Two to 3% of patients with early HSV encephalitis have normal CSF.^{225,285} Repeat analysis of CSF usually reveals abnormalities consistent with encephalitis. HSV is rarely cultured in cell culture from lumbar CSF in patients outside the neonatal age range and rarely has

FIG. 158.11 Electroencephalogram in a 9-month-old infant with herpes simplex virus encephalitis. Note the paroxysmal discharges, especially in lead 12.

been grown from ventricular fluid.¹⁴¹ Thus, whereas CSF examination is helpful, it is not at all diagnostic of HSV encephalitis. When the CSF of patients with HSV encephalitis is compared with that of patients undergoing biopsy for suspected HSV but with another resultant diagnosis, no differentiating characteristics of CSF are found that could allow one to predict HSV infection accurately. HSV DNA can be detected by the use of PCR assay of the CSF of patients who have HSV encephalitis and is currently the diagnostic test of choice.^{9,24,115,120,236,339,418}

Neurodiagnostic tests may support the diagnosis of herpes encephalitis. One useful test for early changes associated with herpes encephalitis is the electroencephalogram (EEG) (Fig. 158.11).³² A “typical” pattern of unilateral or bilateral (poor prognosis) periodic focal spikes against a background of slow (flattened) activity (paroxysmal lateral epileptiform discharges [PLEDs]) has been associated with HSV encephalitis.²⁰⁹ These findings are suggestive but not pathognomonic. Other findings include large-amplitude, irregular slow activity, sharp waves, and variable spikes. In 80% to 90% of patients, the EEG is not only abnormal but also localizing. In many cases in the pediatric and adult age groups, the EEG may be one of the earliest localizing laboratory tests.^{117,156,223} Less commonly, the results of a radionuclide or computed tomographic (CT) scan are abnormal and localizing (50–60% of cases).^{205,250}

CT results may be characteristic late in the illness and consist of low-density, contrast-enhanced lesions in the temporal area, mass effect, edema, and hemorrhage (Fig. 158.12); early in the illness, when establishing the diagnosis is critical, CT results more often are unremarkable.^{156,223,279} Abnormal CT results are a poor prognostic factor.²⁷⁹

MRI findings are more likely to be abnormal at initial evaluation for HSV encephalitis because of its high sensitivity to changes in brain water content³⁶⁷ (Fig. 158.13), and MRI is more sensitive than is CT for detection of HSV encephalitis.^{114,319} Findings include hyperintensity of the temporal and brain stem areas on T2-weighted MR images, and imaging results may be normal if performed in the early stages of the disease.^{4,209}

Focal abnormalities in HSV encephalitis are significantly more likely to be observed on EEG, CT, or MRI than in other illnesses confused with it. All these findings are biased by the current concept of HSV encephalitis as a focal encephalitis, with very few biopsy data available on the etiology of nonfocal encephalitis. Studies using EEG, MRI, and PCR technology have identified cases with multifocal brain involvement.^{469,250,360}

Clinical and laboratory evaluations of patients with suspected HSV encephalitis are valuable only for increasing the index of suspicion, not for confirming the diagnosis. In one series of 24 children with HSV encephalitis diagnosed by PCR assay and compared with 38 children in whom HSV encephalitis was excluded by PCR, no significant differences were found in clinical manifestations at onset or in CSF cell

counts, protein, or glucose.¹⁸⁹ However, more children with HSV encephalitis had localizing findings detected by CT (75% vs. 31%), whereas 36% of those without HSV encephalitis had EEG abnormalities as opposed to no EEG abnormalities detected in those with HSV encephalitis.

The differential diagnosis of HSV encephalitis is large (Box 158.1). Especially in the pediatric age range, the ability to discriminate HSV encephalitis from other etiologic agents mimicking it is poor (50% in the national collaborative series in 71 patients <20 years and 42% in a smaller series of 12 patients <12 years).²²³ Confirmation of the specific diagnosis of HSV encephalitis remains essential, both to provide optimal aggressive therapy for that condition and, of equal importance, to achieve a diagnosis for the 50% to 60% of patients without HSV infection, roughly 16% of whom would benefit from other specific therapies.^{117,223,279,453} In most cases, the diagnosis can be established by PCR analysis of CSF.^{9,24,159,236,339,360,362,423} Large studies show PCR analysis to be 98% sensitive and 94% specific when compared with brain biopsy.^{159,236}

FIG. 158.12 Computed tomographic scan 1 week after the onset of herpes simplex virus encephalitis in a 6-year-old child. Note the bilateral temporal low-density areas with dye enhancement and the greater mass effect on the patient's left side compared with the right side.

PCR analysis may yield positive results by 1 day after the onset of symptoms.¹⁵⁹ However, a negative PCR result obtained soon after the onset of symptoms does not exclude the diagnosis of HSV encephalitis. In two small series of patients, repeat testing of CSF 4 to 7 days after an initial negative HSV PCR assay showed positive PCR results.⁴⁴⁷ HSV DNA persists in most specimens for a week or more, even after antiviral therapy.^{418,452} PCR primers must be chosen to detect HSV-2, as well as HSV-1, because 4% to 6% of HSV encephalitis cases may be caused by HSV-2.²⁵

If PCR results are negative in a patient who has symptoms and signs of HSV encephalitis, repeat CSF HSV PCR analysis should be performed. If this is still negative, and the patient's condition is progressively worsening, brain biopsy may be contemplated, in addition to other diagnostic tests on CSF. A negative HSV PCR on the CSF does not exclude the diagnosis of HSV encephalitis. In the national collaborative study of 432 biopsies, six complications occurred after brain biopsy (hemorrhage in three patients and poorly controlled brain edema in three, for a 1.4% complication rate).⁴⁵⁶ Roughly 2% to 3% of brain biopsies yielded false-negative results, usually because of biopsy of the wrong site.⁴⁵⁶ Decision analysis suggests that performing a biopsy is especially critical in a patient with low CSF glucose levels.³⁵⁶

Quantitative PCR analysis may have value as a prognostic tool and as a method of assessing the response to antiviral therapy in patients with HSV encephalitis.^{15,452} In 16 patients, those with high copy numbers of HSV DNA in CSF tended to have abnormal CT scans, be older, and exhibit more severe sequelae. HSV DNA levels were found to decrease during acyclovir therapy in seven patients; the exception was a patient whose copy numbers increased and who subsequently had a fatal infection.

A less acute form of HSV encephalitis, with indolent presentation, in immunocompromised patients has been reported. Also less commonly, HSV has been implicated in brain stem encephalitis.¹²⁹

Relapse occurs in approximately 5% of treated patients.²²³ Choreoathetosis may be an initial sign of relapse.^{230,441} Reports of a postherpetic encephalomyelitis caused by a probable autoimmune or demyelinating etiologic factor have appeared^{2,13,220}; moreover, virus-positive recurrence of HSV encephalitis has been described months after patients have undergone apparently successful therapy.¹¹⁸ HSV encephalitis may recur, after successful treatment and suppression, in neonates, as well as in children and adolescents.¹⁷⁸

Infection of the Gastrointestinal Tract in Normal Hosts

Whereas infection of visceral organs is well recognized in immunocompromised hosts, case reports of such infection in apparently healthy

 Alcoholic encephalopathy
 Leukemia
 Cerebral infarction
 Subdural or epidural hematoma
 Adrenal leukodystrophy

persons are less common. Nonetheless, HSV esophagitis has been described in patients, including several children who were 11 months to 17 years of age.^{19,31,67,144,278,301} Esophagitis has recently been reported as complication of wrestling.²⁰⁸ HSV-1 is the usual pathogen, and the syndrome is associated with primary infection.¹²² Initial symptoms include fever, severe odynophagia, retrosternal and subxiphoid pain, and an inability to eat. Oral lesions may be present, but skin lesions generally are absent. Esophagoscopy reveals ulcerations and fibrinous

and, at times, hemorrhagic exudate. Distal involvement may be more extensive than the proximal esophageal findings suggest. Double-contrast esophagography may be diagnostic, although endoscopy and biopsy usually are necessary for establishing a definitive diagnosis. Symptoms generally remit in 5 to 7 days after the administration of acyclovir and nonspecific therapy such as antacids, histamine-2 blockers, and hydration.^{19,67,278} Perforation of the esophagus is a rare complication.

HSV infection can manifest as an anorectal infection in males who have sex with males.^{153,321} In most series of HSV proctitis, cases are in younger adolescent males involved in passive anal intercourse. This syndrome occasionally affects women practicing passive anal intercourse. Initial symptoms include severe anorectal pain, discharge, tenesmus, hematochezia, and, in particular, fever, difficulty urinating, sacral paresthesias, constipation, and (in 50–70% of patients) ulcers or vesicles in the perianal or distal rectal area.¹⁵³ The duration of symptoms is 2 to 3 weeks. Primary HSV infection accounts for proctitis in this group in 25% to 30% of cases. Syphilis and infection with *Giardia lamblia*, *Entamoeba histolytica*, *Campylobacter fetus*, *Shigella* spp., other enteric bacteria, and *Neisseria gonorrhoeae* also must be considered in the differential diagnosis of this entity. Appropriate cultures and histologic analysis are crucial for establishing a specific diagnosis.

HSV is a rare cause of hepatitis and represents a broad spectrum of disease from mild elevation of aminotransferases to fulminant liver failure and death. HSV-1 and HSV-2 should always be considered in the differential diagnosis of acute liver failure.⁴²⁷ HSV hepatitis occurs in all ages from neonate to adult, in pregnancy, and in both immunocompetent and special hosts.^{30,269,275} In one review of the literature describing 35 patients who had HSV-associated hepatitis, 14% had no underlying condition. The remainder had various immunocompromising conditions such as transplantation, corticosteroid administration, pregnancy, burns, primary immunodeficiency, or cancer. These patients tended to have fulminant hepatic necrosis, extremely elevated serum aminotransferase levels, disseminated intravascular coagulation, and a mortality rate of 86%.⁸⁵ In a prospective study of healthy young adults with genital herpes (primary or recurrent), 14% had mild elevations in liver enzyme tests.

Recurrent Infections

HSV-1 and HSV-2 have the characteristic capacity of herpesviruses to establish latency and undergo episodes of reactivation despite the presence of an apparently adequate immune response. Persistence is facilitated because latent infection of neurons occurs in an immunologically “privileged” site. Reactivation of HSV infection with viral shedding generally causes no lesions. HSV can be recovered from the pharynx and genital sites of asymptomatic persons. It has been found in the tears of persons with a history of recurrent ophthalmic disease, even in the absence of eye lesions or symptoms. All HSV-2-seropositive women from whom samples of vaginal secretions were obtained for more than 100 days had documented asymptomatic viral shedding, and shedding occurred on 1% of the days on which cultures were performed.⁴⁴⁰

Patterns of HSV reactivation include asymptomatic reactivation after silent primary infection, asymptomatic reactivation after symptomatic primary infection, and symptomatic recurrence after either silent or symptomatic primary infection. The risk for having symptomatic recurrences may be higher in individuals who have symptomatic primary infections. When reactivation causes disease, the clinical manifestations of recurrent HSV infection depend on the area involved. Most HSV recurrences are milder than the primary illness, although patients may have symptomatic recurrences without having had clinically apparent primary disease. Recurrent infection in a normal host also may be more severe than is the primary infection. This pattern is particularly evident in HSV infection of the eye, in which recurrent illness is associated with deep stromal damage and scarring.^{315,475} This enhanced severity may be related to a greater extent to a more exuberant immune response than to viral damage. HSV encephalitis, which may be a manifestation of viral reactivation, is devastating.^{285,334}

The most common manifestation of recurrent HSV infection is herpes labialis (“cold sores,” “fever blisters”). Recurrences are observed in 25% to 50% of persons who have had symptomatic primary HSV-1 oral infection but in only 24% of those who had primary HSV-2 oral

FIG. 158.14 Recurrent herpes labialis (cold sore) in an adolescent.

infection. The mean rate of recurrence after symptomatic primary HSV-1 infection in adults is approximately 0.1 per month. These recurrences often are associated with a variety of febrile illnesses, local trauma, sun exposure, or menstruation.^{27,382,385} Whether acquisition of HSV-1 in childhood is less likely to be associated with recurrent herpes labialis is not known.

Most persons with herpes labialis experience a prodrome (pain, burning, tingling, or itching) at the site that lasts a few hours to several days. Subsequently, an orderly progression ensues from papules (lasting 12 to 36 hours) to vesicles (usually gone by 48 hours) and finally to ulcers and crusting (lasting 2 to 4 days) (Fig. 158.14). The typical lesion measures 35 to 80 mm. The majority of outbreaks are healed by 5 to 10 days (mean, 200 hours). Most pain occurs during the vesicular stage. Virus is isolated readily from vesicles (80–90% of the time) and less commonly from ulcers and crusts (34% of the time). Maximal virus titers (10^7 to 10^8) in lesions are detected in the first 1 or 2 days, and virus generally is not isolated after 120 hours.^{27,385} Virus is detected in the saliva and on the hands of persons with herpes labialis.

Recurrences tend to affect the same location or closely related areas. In general, they occur on the lips, mucocutaneous junction, or other parts of the face. Recurrent lesions found inside the mouths of normal hosts rarely are caused by HSV and more likely are aphthous lesions. When HSV recurrences are within the mouth, they tend to be on tissue adjacent to bone, such as the gums or palate, and not on the lips or buccal mucosa.³⁸⁰ A differential diagnosis of the condition also includes pemphigus, lichen planus, ulcers caused by cyclic neutropenia, and ulcers associated with celiac disease, ulcerative colitis, Crohn disease, pernicious anemia, and Behçet syndrome.

Recurrent genital herpes is the second most common manifestation of HSV. Studies have elucidated several factors that increase the risk for recurrent genital disease after symptomatic primary genital infection. Recurrence rates are much higher after primary HSV-2 (90%) than after primary HSV-1 (25–55%) infection.^{234,326} The mean rate of recurrence is 0.02 to 0.1 per month after primary genital HSV-1 infection and 0.3 per month after primary HSV-2 genital infection.^{234,326} Recurrences are seen more commonly in men than in women and more commonly after a recurrent lesion than after a first attack.³²⁶

Only 5% to 12% of persons with recurrent genital herpes have constitutional symptoms. Local symptoms include pain (average, 4–6 days), itching, dysuria (10–30%), adenopathy (20–30%), and lesions (average, 50–60 mm) lasting 4 to 5 days until crusting, with healing taking place by 9 to 11 days (range, 4–29 days) (see Fig. 158.3). Symptoms in females tend to be more severe than those in males. Virus is shed for an average of 3 to 4 days (but in some cases as long as 20 days). Virus generally is shed with titers of 10^2 to 10^4 per lesion. Vesicles are seen in dry areas, but in wet areas the vesicles rapidly break down into ulcers. Symptoms generally are milder and of shorter duration than those in primary genital disease.⁵⁵ New crops of lesions commonly occur during the course of recurrence. The severity of recurrence is quite variable; in some cases, several discrete recurrences blend into a single, prolonged recurrence, and in rare cases, patients have almost continuous recurrences.¹⁶⁰ In one study of patients who were HSV-2 seropositive with no history of genital herpes, 62% had recognized herpetic lesions at later evaluation.⁴⁴⁰ Recurrences in the previously asymptomatic group were shorter (3 vs. 5 days) and less frequent (3.0 vs. 8.2 per year) when the pattern of recurrence in this cohort was compared with that of subjects with a known history of genital herpes.

With endonuclease restriction analysis, researchers have clear evidence that, whereas most recurrences represent endogenous reactivation of the same latent virus, reinfection with a new homologous virus (i.e., HSV-2 and new HSV-2), as well as heterologous virus (i.e., HSV-2 and then HSV-1 or vice versa), is possible.⁶⁵ How common this occurrence is remains to be ascertained and must depend to some degree on the sexual activity and number of partners of the persons studied.³⁶⁴

Other cutaneous recurrences may develop at each anatomic site of primary infection. HSV infection may recur on the face or trunk in a typical dermatome distribution, such as that associated with VZV. Indeed, frequent repeated attacks of zosteriform lesions on any part of the body in a normal host suggest HSV and not VZV infection.

Erythema Multiforme

Erythema multiforme is thought to be an immune-mediated, “allergic” response to recurrent HSV infection.^{138,185,276,296,449} It has been associated with the presence of human leukocyte DQw3 antigen.²⁰⁴ In several series, approximately 15 to nearly 100% of patients who have erythema multiforme, especially those with recurrent erythema multiforme, gave a history of recurrent HSV infection before the skin eruption, which may be macular or urticarial.¹⁸⁵ In one series, five of 80 patients who had recurrent oral HSV infection experienced a rash (presumably erythema multiforme) that manifested 8 to 14 days after the onset of a cold sore.³⁸⁵ Studies in adults and children have documented HSV antigen-antibody immune complexes and HSV DNA (detected by PCR analysis and in situ hybridization) in the skin of patients who had erythema multiforme after having HSV infection.^{49,50,296} In a series of 20 children with erythema multiforme (10 who had antecedent herpes), 16 were documented to have HSV DNA at the site of the rash.⁴⁴⁹ The mechanism of transport of viral DNA fragments is not clearly understood. Recent studies suggest that CD34⁺ cells play a role in transport of HSV DNA fragments to lesional skin.²⁹⁵

The skin manifestations may last 14 to 21 days, and therapy generally is directed toward the allergic and not the viral component of the illness. Suppression of HSV recurrences prevents the associated episodes of erythema multiforme. Indeed, suppressive treatment of erythema multiforme with acyclovir, even in the absence of recurrent HSV infection, completely suppresses clinical manifestations.^{366,406} In one series, the syndrome developed in 12 children at a mean age of 8 years within 4 days after the appearance of herpes labialis lesions and symptoms lasted for an average of 10 days; nine children had recurrent erythema multiforme, with an average of 2.6 episodes per year.⁴⁴⁹ Detection of HSV by PCR assay of skin biopsy tissue was described in all cases. None of three children given acyclovir suppressive therapy had recurrences during treatment for at least 6 months, but erythema multiforme with recurrent HSV developed in one child when use of the drug was discontinued, thus supporting a causative role of HSV in the syndrome.

HSV Infection in Immunocompromised Hosts

application of bone marrow and organ transplantation, HIV infection, and increasingly intensive therapy for malignancies, tumors, and primary immune deficiency disorders, the prevalence of severe HSV infection in immunocompromised hosts is increasing.²⁷¹ Box 158.2 lists conditions associated with unusually severe HSV infections. Aside from several cases of HSV encephalitis in patients with agammaglobulinemia (who also had concomitant infections with enterovirus),²⁵⁶ common links in these varied groups are either skin abnormalities (eczema, burns) or immunologic defects, primarily in the cell-mediated components of the immune system.^{43,140,179,312,387,410} The critical defects have not been defined and may involve one or a combination of inadequate functions (e.g., of CD4⁺ T cells, CD8⁺ T cells, natural killer cells, macrophage antigen processing, or other factors).

The incidence of severe HSV infection in children with diseases that predispose them to these complications (see Box 158.2) is defined poorly but, in limited series, was similar to that seen in adults.^{143,151,323,334} Most infections are caused by reactivation, as would be expected given the relative frequency of primary and recurrent infections.

In series of pediatric or adult patients who have received renal, bone marrow, or cardiac transplants, 70% to 90% of seropositive persons excreted HSV, usually from the oropharynx and generally at the time of peak immunosuppression (in the first month after transplantation).²⁸⁷ HSV disease usually occurs within 2 to 3 weeks of solid organ or hematopoietic transplantation in patients who do not receive antiviral

prophylaxis.¹⁵¹ Of 68 children who underwent renal transplantation, a herpesvirus was isolated in 43%, with 28% of the isolates being HSV.⁴¹⁶ HSV in cardiac transplant cases causes symptomatic illness in 45% to 85% of seropositive patients, depending on the intensity of immunosuppression. HSV was the virus most commonly isolated in children who underwent bone marrow transplantation (23%).⁴⁴⁴ HSV has been suggested to be one of the etiologic agents of the interstitial pneumonitis that can develop after bone marrow transplantation.^{290,324} In children with leukemia, HSV infection occurs more commonly in those with myelocytic leukemia than in those with lymphocytic leukemia, and the risk for the development of infection increases with neutropenia and chemotherapy. HSV infection was the most common serious viral infection in children with leukemia. Whereas most infections occurred during periods of remission, on a per-day basis, the risk for development of infection was seven times higher during induction.⁴⁶⁹

In Africa, patients suffering from underlying malnutrition and concomitant measles infection may contract fatal disseminated HSV infection; such events rarely occur in industrialized nations.^{34,215,410}

In children with HIV infection, HSV causing chronic mucocutaneous ulcers (persisting for more than 1 month), bronchitis, pneumonitis, and esophagitis is an AIDS-defining condition.⁸⁰ Chronic ulcerative HSV lesions often develop in children with HIV infection.³⁵¹ Chronic HSV mucocutaneous disease or widespread organ involvement was reported as the AIDS-defining condition in seven of 789 (0.9%) HIV-infected children in one analysis.⁴²⁰ In another series of children with AIDS, five to 29% contracted HSV opportunistic infection.¹⁴³ Many of these children have perianal ulcers from which HSV-1 is isolated. In HIV-infected patients, dissemination is a rare occurrence.²⁰ Multiple recurrences of infection are common as the immunodeficiency worsens. In patients with AIDS, HSV can cause a typical^{165,428} or more indolent encephalitis. HSV usually does not result in mortality in HIV-infected patients, but it causes significant morbidity.²¹⁷ HSV genital ulcer disease increases the risk for acquisition of HIV.¹⁸² Studies show that suppression of clinical and subclinical reactivation of HSV is associated with a decrease in HIV viral load.³⁵⁷ In one recent study, daily acyclovir therapy did not reduce the risk for transmission of HIV-1, despite a reduction in plasma HIV-1 RNA and a 73% reduction in the occurrence of genital ulcers due to HSV-2, suggesting that a more substantial reduction in plasma HIV-1 RNA is necessary to reduce transmission.⁷⁷

Several major syndromes are attributable to HSV in immunocompromised patients, with some overlap and occasionally progression from one to another. The first and most common manifestation is a local, chronic, often extensive cutaneous or mucocutaneous infection. The second form is infection involving a single organ (e.g., esophagitis or pneumonitis). The most serious illness is characterized by more widespread dissemination involving distant areas of the skin or visceral organs (e.g., the lungs, liver, adrenal glands) and the CNS. Although data are limited, disseminated disease probably most often represents primary infection except in the most severely immunocompromised patients. More localized syndromes may be a manifestation of either primary infection or recurrent illness.²⁷¹

The typical localized HSV infection begins in the mouth or about the lips, often appearing innocuously as recurrence of ordinary herpes labialis. Over the course of several days, the papules and vesicles progress to bullae, frequently with hemorrhagic fluid. The bullae or vesicles evolve into huge, chronic, bloody, coalescing, ulcerated, oozing lesions eroding into subcutaneous tissue and occasionally destroying underlying structures. The tissue is malodorous, and the lesions are painful (Fig. 158.15). The lip and palate are the sites most commonly affected. Oral lesions account for approximately 60% of HSV infections in children undergoing transplantation.⁴¹⁶ A similar syndrome, usually caused by HSV-2 infection, may be seen in the perianal or vaginal area and is one of the characteristic syndromes that occur in males who have sex with HIV-infected males (Fig. 158.16). If untreated, the lesions may lead to death because of local destruction and hemorrhage, or they may regress as the immune status of the host improves or as antiviral chemotherapy is administered. A syndrome of herpetic geometric glossitis has been reported in HIV-infected patients.¹⁵⁸ Affected patients have a tender tongue accompanied by dorsal longitudinal crossed and branching fissures.

FIG. 158.15 Chronic hemorrhagic herpes simplex virus infection in a girl with leukemia who had received a bone marrow transplant.

FIG. 158.16 Herpes simplex virus proctitis and rectal infection in a homosexual male with AIDS. (Courtesy Dr. Victor Fainstein, Department of Internal Medicine, MD Anderson Cancer Center, Houston.)

Extensive HSV skin infections may occur in patients with burns, eczema, pemphigus, or abrasions, often with conversion of second-degree tissue damage to third-degree damage (see Figs. 158.6 and 158.7). Of 179 children with eczema, herpes skin infections developed in 10, seven of whom required hospitalization.¹⁰⁸ Although rare, local infection may progress to dissemination in some cases, possibly as a result of the more severe immunodeficiency occurring with several of these conditions. The widespread necrotizing lesions are known commonly as *Kaposi*

varicelliform eruption or *eczema herpeticum* (see Fig. 158.6). The predisposition to severe HSV-1 infection in children with atopic eczema appears to be due to the cutaneous abnormalities because these children have T-cell responses to HSV, as well as high HSV IgG antibody titers.¹⁵⁴ Studies have looked at the role of the cathelicidin family of antimicrobial peptides in protecting children with atopic dermatitis against disseminated skin infection with HSV. Variable skin expression of cathelicidin peptide LL-37 may explain why eczema herpeticum develops in some children with atopic dermatitis and others appear to be at lower risk.^{154,183} One study evaluating phenotypic risks for eczema herpeticum demonstrated that children with severe atopy and greater T-helper type 2 (Th2) polarity (as demonstrated by an increase in Th2 chemokines) were at increased risk for HSV and *Staphylococcus aureus* skin infections.³³

Herpes skin lesions must be differentiated from bacterial infections caused by gram-positive or gram-negative organisms, chronic fungal infections (as seen with *Mucor* or *Blastomyces*), other viral infections (vaccinia, varicella), mycobacterial infection, and various noninfectious lesions such as pyoderma gangrenosum, chemotherapy-induced ulcers, or Sweet syndrome.

HSV esophagitis rarely has been reported in normal children,^{31,67,208} but it is a relatively common finding in immunocompromised patients. Pathologic studies have suggested that approximately 25% of cases of autopsy-proven esophagitis (1–6% of all autopsies) are secondary to HSV infection (14 of 55 cases).²⁸⁹ Underlying conditions included burns, aplastic anemia, malignancies, transplantation, a variety of other serious medical problems, and postoperative trauma induced by nasogastric tubes.^{67,262,289} Twenty to 50% of these patients have HSV involvement elsewhere (the lungs, trachea, and, less commonly, the skin). The esophagitis may be asymptomatic or associated with dysphagia, odynophagia, epigastric discomfort, and retrosternal pain. Characteristic findings in the esophagus are ulcers with raised granular margins. The ulcers often are covered with fibrinous exudate and, in advanced cases, are confluent, with progression to complete mucosal loss in large segments of the esophagus. Typically, visceral herpes infection is not suspected before the patient's death, but, uncommonly, involvement of adjacent gastric tissue can be documented. Diagnostic evaluation should include a barium swallow, which may demonstrate edema, nodules, and ulceration of the esophagus; however, barium studies cannot differentiate HSV from other etiologic agents of esophagitis. Esophagoscopy accompanied by biopsy and viral culture is diagnostic and helps exclude other common causes of this syndrome, including *Candida*, CMV, and possibly other fungi and bacteria or chemotherapy-induced changes.^{66,67,289} Although the oral cavity, esophagus, and rectum are the usual sites of HSV infection in the gastrointestinal tract of immunocompromised patients, HSV-2 colitis has been reported in a young child after combined liver and small bowel transplantation.¹¹³

HSV pneumonia is an unusual condition, but lung involvement has been described in neonates⁴¹ and immunocompromised hosts. This diagnosis frequently is made post mortem almost exclusively in immunocompromised patients. In one series of 1000 consecutive autopsies,²⁸⁸ HSV pneumonia was identified in 10 cases. HSV pulmonary infection occurred in 3% of children who had undergone renal transplantation.⁴¹⁶ In most adult cases, the process is a result of endogenous viral mucocutaneous reactivation and involvement of lung tissue by contiguous spread, which causes focal pneumonia (60% of the time), or involvement by hematogenous spread from an oral or genital site, which results in diffuse pneumonitis.³²⁴ Although the largest series consisted primarily of adult patients, three of the patients were aged 7 years or younger (with Down syndrome and congestive heart failure, rhabdomyosarcoma, and pneumococcal pneumonia and a seizure disorder).¹⁸⁷ Patients had cough, dyspnea, fever, and hypoxia; and 50% had rales. Most had other concomitant pulmonary infections with bacteria, *Candida*, *Aspergillus*, and CMV. HSV pneumonia cannot be diagnosed by the association of upper airway cultures and radiographic abnormalities. It must rest on an aggressive approach involving culture and histopathologic examination of involved lung tissue obtained by either biopsy or bronchoscopy.

HSV meningoencephalitis is not a common occurrence in immunocompromised patients. It may occur as a component of widely

disseminated disease, or it may be a localized condition. Several cases have been reported in patients who had agammaglobulinemia in association with concomitant enteroviral infection of the brain.²⁵⁶ The meningoencephalitis may be fulminant, such as occurs in a normal host. An interesting case that followed an atypical subacute course accompanied by bilateral brain involvement has been reported in an anergic patient who had Hodgkin disease. HSV encephalitis may also involve the brain stem.²⁵⁷ Although HSV does not appear to have a predilection for CNS infection in immunocompromised hosts, patients with AIDS are an exception and may have ascending myelitis, acute transverse myelitis, and encephalitis.^{143,146,165,428}

Hepatitis caused by HSV has been reported most commonly after solid organ or bone marrow transplantation^{85,197,231} and during pregnancy.²¹⁶ Signs include fever, abdominal pain, and elevated liver enzyme levels. Hepatitis usually occurs during the first 3 weeks after transplantation, unless prophylactic acyclovir is given. The mortality rate is very high (67–100%). In at least one case, orthotopic liver transplantation resulted in survival.³⁷¹ HSV is reported as the most frequently identified viral etiology of hepatitis on one series of patients with systemic lupus erythematosus.³²³

The most severe form of HSV in an immunocompromised host is widely disseminated disease that can involve the liver, adrenals, lungs, spleen, kidney, and often the brain. In studies from South Africa and Kenya,^{34,215,410} measles and severe malnutrition were frequent cofactors in children who had widely disseminated HSV infection. These illnesses represented fatal primary infections. Similar syndromes have been described; they and other underlying conditions are listed in Box 158.2. Dissemination has been reported coincident with *Bordetella pertussis*, *Haemophilus influenzae* meningitis,¹⁹⁴ and other bacterial infections.³⁴ Disseminated HSV infection occurred in 10% and 25% of children who had HSV infection and underwent bone marrow and renal transplantation, respectively.^{287,444}

Disseminated HSV infection initially usually manifests as initial fever and skin or mucocutaneous involvement in 80% of cases, but instead of healing as expected, the infection disseminates. The cutaneous dissemination may involve a widespread vesicular eruption that looks much like varicella, or it may involve more local, large hemorrhagic vesicles and bullae. Involvement of the major target organs, as noted previously, gives rise to syndromes of hepatitis, pneumonia, shock, bleeding, disseminated intravascular coagulopathy, seizures, coma, renal failure, hypothermia, and death in days to weeks. Laboratory examination may reveal leukopenia, thrombocytopenia, elevated liver function test values, hyponatremia, azotemia, pneumonitis, hypoglycemia, CSF pleocytosis, abnormal EEG results, and electrocardiographic abnormalities. Death occurs commonly in this syndrome (90%), even after the institution of antiviral chemotherapy. Because the liver frequently is involved and biopsy may be precluded by the tenuous condition of the patient, HSV infection should be considered in all high-risk groups (see Box 158.2) with fulminant hepatitis.

Fetus and Newborn

HSV may infect the fetus before delivery (congenital or in utero infection), infect the newborn during delivery (perinatal or natal infection), or infect the infant after birth (postnatal infection).

The clinical spectrum in infants with in utero acquired, congenital HSV infection is different from that observed in infants with natal or postnatal disease. The classic triad of cutaneous findings, CNS disease, and ophthalmologic disease is seen in approximately one third of neonates with congenital HSV.²⁶⁵ The most prominent and most common features of congenital infection are vesicular rash, bullae, or cutaneous scars present at birth or within a few days of birth. In some cases, the extent and severity of these lesions may result in an initial diagnosis of epidermolysis bullosa. At least one case report of limb hypoplasia, similar to congenital varicella syndrome, has been shown to be caused by HSV-2.¹⁹⁶ Two thirds of infants demonstrate extensive involvement of the CNS at birth, either clinically or from autopsy findings: diffuse brain damage, microcephaly, or intracranial calcifications. In some infants, eye findings have been noted, including chorioretinitis, microphthalmos, retinal scars and retinal dysplasia, and cataracts.

The three general patterns of natal or postnatal neonatal HSV infection are categorized by the extent of disease: (1) disseminated infection with or without CNS involvement, present in 25% of cases; (2) infection localized to the CNS, in 30% of cases; and (3) infection localized to the skin, eye, or mouth, in 45% of cases.

Infants with natal or postnatal HSV infection commonly have a clinical picture resembling that of bacterial sepsis: alterations in temperature, lethargy, respiratory distress, anorexia or vomiting, and cyanosis. In febrile neonates presenting to an acute care treatment center, HSV infection should be considered in the differential diagnosis of neonatal fever, especially in the presence of mononuclear CSF pleocytosis, hypothermia, or sepsis-like syndrome.⁷²⁻⁷⁴ If skin involvement is present, then skin vesicles or mucous membrane ulcers may be apparent. If the conjunctivae or cornea is involved, then nonexudative conjunctivitis, tearing, and pain will be present. If the CNS is involved, then seizures may occur.⁴⁴² The frequency of disseminated disease has decreased after a high of 51% reported in the years 1973 to 1981; this decrease probably represents earlier diagnosis and treatment of localized infection before dissemination occurs.⁴⁵⁷ The disseminated form of infection in the earlier years of recognition presented in infants between 9 and 11 days of age and usually involved the liver, where it caused fulminant hepatitis with disseminated intravascular coagulation, and the adrenal glands, and it most closely resembled the picture of bacterial sepsis.⁴²⁷ Current reports show disseminated neonatal HSV may present as early as the first week of life, without cutaneous or localizing signs, similar to bacterial sepsis, and confirm that HSV remains an important cause of neonatal morbidity and mortality. A disseminated infection can affect multiple organs, including the brain, larynx, trachea, lungs, esophagus, stomach, lower gastrointestinal tract, spleen, kidneys, pancreas, and heart. Pneumonia occurs in 37% of infants. Markedly elevated aminotransferase levels, direct hyperbilirubinemia, coagulopathy, and thrombocytopenia are common findings late in the disease process. From 60% to 75% of infants with disseminated disease have hematogenously acquired CNS involvement and meningoencephalitis, as manifested by irritability, a bulging fontanelle, localized or generalized seizures, flaccid or spastic paralysis, opisthotonos, decerebrate rigidity, or coma. Importantly, 39% of infants with disseminated disease do not have skin vesicles or eye lesions at initial evaluation, and vesicles do not develop during the acute HSV disease; only 56% initially have fever, and many are hypothermic on presentation.

CNS disease from retrograde axonal transmission of virus presents later than does disseminated disease, usually when the infant is 11 to 17 days old but occasionally when the infant is as old as 4 to 6 weeks of age. Typically, these infants have focal seizures that subsequently generalize. Examination of CSF demonstrates mononuclear pleocytosis with a predominance of lymphocytes, a moderately low glucose concentration, and elevated protein levels. A normal cell count, glucose, and protein concentration, however, may be found on the initial lumbar puncture, if performed early in the disease process. An elevated red blood cell count secondary to hemorrhagic brain involvement may be present but by itself is an unreliable sign. Fever is present at initial evaluation in only 44% of infants with HSV encephalitis, and 32% of infants do not have skin vesicles either initially or during the course of their illness. Neonatal HSV encephalitis can be disseminated to all parts of the brain, multifocal in many parts of the brain, or limited to only the temporal lobes, brain stem, or cerebellum; and watershed distribution ischemia may be seen in some cases.^{309,430} Delayed recurrence of HSV infection of the central nervous system may occur once the newborn recovers and has completed 6 months of antiviral suppressive therapy.¹⁷⁸ Recurrence in the CNS has been reported to occur as long as 7 years after neonatal herpes simplex virus CNS disease.^{26,178}

Localized skin, eye, or mouth disease usually presents within the infant's first 7 to 10 days of life. Approximately 83% of these neonates have skin lesions: usually single vesicles, occasionally vesicle clusters, and rarely a zoster-like rash. As many as 46% to 80% of neonates with skin lesions have one to 12 recurrences during the first 6 to 12 months of life. Thirteen to 25% of infants have eye involvement; disease is limited to only the eye in one third of these cases, but the risk for disseminated disease is significant.⁴⁴² Common manifestations include eye pain and eyelid swelling, fussiness, tearing, nonexudative

conjunctivitis, keratitis, and chorioretinitis. As many as 83% of infants are afebrile initially. One third of all infants have evidence of herpetic mouth lesions.

Unusual manifestations of HSV infection in the neonate, from perinatal or postnatal sources, also include conjunctivitis with keratitis, laryngotracheobronchitis, pneumonitis, and epiglottitis.²⁶³

DIAGNOSIS

Clinical findings may suggest a probable diagnosis of HSV infection, but obtaining a definitive laboratory diagnosis is necessary or useful in many circumstances and should always be sought in neonates and patients with severe disease.^{17,75} Accurate laboratory diagnosis requires giving attention to obtaining the correct specimens necessary for identifying the etiology of the clinical syndrome. Appropriate interpretation of the laboratory results is the second critical factor. Evaluation of mucocutaneous lesions in high-risk patients guides the use of antiviral therapy if the lesion is herpetic. However, because HSV often is shed in immunosuppressed and otherwise healthy individuals, finding HSV in oropharyngeal secretions does not mean that the clinical condition is caused by HSV. In general, the virus must be isolated from the relevant tissue or involved end organ for confirmation of the diagnosis. The test selected also is important (e.g., HSV is rarely found in CSF cultures of patients outside the neonatal age group with HSV encephalitis but often is present in aseptic lymphocytic meningitis caused by HSV). Detection of HSV DNA in CSF by PCR assay or by brain biopsy is indicated to prove the diagnosis and exclude other treatable causes of encephalitis. Laboratory diagnosis also is valuable when HSV infections are not life threatening.⁷⁵ For example, establishing that a genital lesion is caused by HSV-1 or HSV-2 facilitates decisions about antiviral therapy and allows initiation of appropriate counseling regarding the risk for recurrences and measures that may reduce transmission of HSV to contacts and during pregnancy to the neonate.

Viral Culture

The original gold standard for HSV diagnosis was recovery of infectious virus in cell culture. HSV replicates rapidly in cell culture, typically in 1 to 2 days, and produces a characteristic cytopathic effect (CPE) (Fig. 158.17).^{75,238,350} A variety of cell lines (human fibroblasts, A549, and many others) support HSV replication and are used by diagnostic laboratories to isolate HSV. Although the presence of HSV is suggested by the cell types infected as well as the character and timing of the CPE,

FIG. 158.17 Culture of herpes simplex virus on human fibroblasts demonstrating disruption of the cell monolayer and rounding and enlargement of cells to show the cytopathic effect.

definitive identification of the infecting virus is accomplished via microscopy of fixed cells with immunofluorescence assay with HSV-1- and HSV-2-specific antibodies.

Several culture methods that do not rely on the evaluation of CPE have been devised that provide more rapid diagnosis of HSV than traditional culture. One approach is the use of a genetically modified baby hamster kidney cell line containing a reporter gene encoding β -galactosidase under control of an HSV-specific promoter (enzyme-linked viral inducible system [ELVIS]).^{103,245} Addition of a colorimetric reporter substrate after centrifugation-enhanced infection and overnight incubation allows identification of cells infected with HSV. Similarly, the shell vial method uses centrifugation-enhanced infection of cell monolayers and overnight incubation, followed by immunofluorescence assay staining with HSV-specific antibodies.^{133,188,311,419} Although these methods may reduce the time to result, they are typically less sensitive than traditional cell culture.^{84,201}

HSV culture methods, both traditional and rapid, are being phased out by many diagnostic laboratories and replaced by type-specific nucleic acid amplification tests for HSV-1 and HSV-2 DNA. These tests do not show definitively that infectious virus is present in the specimen but suggest that it is or may have been shortly before the specimen was obtained.

Direct Detection of HSV-Infected Cells

Direct detection methods allow a diagnosis of HSV infection to be established more rapidly than any available HSV culture method.^{17,107,245,363} Direct immunofluorescent assay of cells taken from mucocutaneous lesions is the procedure most commonly used.²⁸⁰ Specimens are obtained by unroofing the lesion, swabbing the exposed base to remove infected cells, and transferring the swab to viral transport media. The collected cells are centrifuged and washed, applied to a glass slide, then fixed and stained with fluorescently labeled, HSV-specific antibodies. This method, the direct viral examination or direct fluorescent antibody (DFA) testing, yields sensitivities, when compared with traditional viral culture, in the range of 61% to 80% with few false-positive reactions.^{75,84} To optimize DFA performance, diagnostic laboratories set criteria for specimen adequacy (e.g., requiring a certain number of basal, parabasal, and intermediate cells from lesion sites), thereby emphasizing the importance of proper specimen collection. Despite these precautions, direct detection of HSV by immunofluorescence remains less sensitive than by culture. Because of this, it is recommended that DFA-negative lesional samples be tested by a more sensitive method to rule out false-negative results.⁷⁵

HSV antigens can be detected directly in clinical specimens by a variety of additional methods including enzyme-linked immunosorbent assays (ELISAs) and immunoperoxidase assays.^{8,51,95,245,280,294,363,426} However, these assays have been replaced in the diagnostic laboratory by nucleic acid amplification tests.

Nonspecific methods such as Papanicolaou (Pap) staining or the Tzanck test have been used in the past to suggest possible HSV infection. Even though these methods may show cytologic changes in specimens obtained from suspected HSV lesions, the diagnosis of HSV should not rely on these methods in current practice because rapid, specific methods are available. Although cytologic examination of HSV lesions reveals typical giant cells and, less commonly, Cowdry type A intranuclear inclusions, these changes also are seen with CMV and VZV. Cytologic changes are identified in approximately 70% of culture-positive specimens, but sensitivity is dependent on the experience of the examiner and may be low.^{283,378} Electron microscopy of vesicular fluid or tissue preparations may reveal the characteristic virus of the herpes family (Fig. 158.18). However, the microscopist cannot differentiate HSV from other herpesviruses, and this diagnostic approach rarely is available as a rapid method. Because selection of antiviral therapy for herpesviruses requires specific identification of the infecting virus, nonspecific methods have limited clinical value in the current era of specific antiviral therapy.

Polymerase Chain Reaction Assays

Type-specific HSV nucleic acid amplification assays, particularly PCR assay, have become the gold standard for HSV diagnosis and have replaced virus culture and direct examination in many diagnostic laboratories. The detection of HSV DNA by PCR is more sensitive than the isolation

FIG. 158.18 Electron microscopic demonstration of herpes simplex virus (HSV) particles in a brain biopsy specimen from a 9-month-old infant with HSV encephalitis.

of virus by culture.^{9,25,181,339,347} In one study of mucosal specimens, the ratio of PCR positivity to virus culture ranged from 3.8:1 in the winter to 8.8:1 in the summer. PCR does not require the presence of infectious virus for detection, and this is one of the great advantages and disadvantages of HSV DNA testing. Given the high sensitivity of HSV PCR, false-positive results may occur, particularly if original specimen contamination occurs at time of collection or if cross-contamination between specimens occurs during performance of PCR assay. However, the implementation of careful molecular diagnostic workflows and the development of the real-time PCR methodology have considerably reduced the risk for false-positive reactions.

The clinical utility of HSV PCR was first demonstrated for the diagnosis of HSV encephalitis.^{25,71,159,213,320,328,339,374,418} Given its high negative predictive value, HSV PCR testing of CSF is often used to rule out HSV infection in patients with suspected herpes encephalitis. However, it is important to recognize that HSV DNA may not be detectable in CSF early in the course of disease.⁴⁴⁷ A single negative test should not exclude the diagnosis of HSV when there is high clinical suspicion, and sequential testing of CSF by PCR has rendered the use of brain biopsy unnecessary in most situations. In one study, HSV DNA was detected by PCR in the CSF of 53 (98%) of 54 patients with biopsy-proven herpes simplex encephalitis and was detected in all 18 CSF specimens obtained before brain biopsy was performed on patients with proven herpes encephalitis.²³⁶ Testing febrile neonates with CSF pleocytosis using CSF HSV PCR assay and empirically treating with acyclovir until PCR test results are known has also been shown to save lives and be cost effective.⁷⁴

PCR assay also has demonstrated the presence of HSV DNA in plasma or whole blood and has been used to diagnose HSV viremia in neonates and in immunocompetent patients with eczema herpeticum and primary herpetic gingivostomatitis, as well as in immunocompromised patients with disseminated disease. PCR analysis also may demonstrate prolonged presence of HSV DNA in genital lesions.⁹⁴ The sensitivity of the PCR method is adequate for detecting asymptomatic shedding of HSV.^{68,93,168} HSV PCR also has utility when the clinical diagnosis is difficult to make, as illustrated by detection of HSV in vitreous fluid¹⁷³ and in unusual mucocutaneous lesions in patients with AIDS.²⁴⁴ HSV DNA may also be quantitated in clinical specimens using PCR-based

methods and used to predict severity of disease, especially in hepatitis and encephalitis, and to follow virologic response in these patients.^{35,68}

Serologic Diagnosis

Serologic methods are used to assess HSV immune status and document whether an individual has been infected with HSV. Because these viruses cause persistent infections, the presence of HSV IgG antibodies may only signify that the individual has latent HSV-1 or HSV-2 (or both) in sensory ganglia and that the virus can be expected to reactivate and intermittently shed. Clinical laboratories use ELISA or immunoblot methods to detect HSV-1 and HSV-2 type-specific IgG antibodies in patient sera. These assays use specific HSV gG antigens and can be used to show whether an individual is infected with HSV-1, HSV-2, or both, but not when the infection was acquired.^{128,175,246,379,401,434} If paired sera are available, these assays are capable of demonstrating type-specific seroconversion, even if a patient is already exposed to a single type. The sensitivities of commercial gG type-specific HSV serology tests range from 90% to 98%, with specificities greater than 94% when compared with Western blot analysis.⁴³⁴ As with any serologic test, false-negative results are more likely early in the course of infection, and false-positive results may occur in patients with a low pretest probability of exposure.

If a patient is seronegative at the onset of symptoms or at initial evaluation, primary HSV infection can be documented by demonstrating seroconversion with paired sera.^{203,222} However, serologic tests are not useful for evaluating HSV recurrence, because IgG antibody titers often do not rise during viral reactivation. On the other hand, increases in IgG antibody titer may occur in the absence of recurrent disease. In addition, testing for IgM antibodies does not improve the serologic diagnosis. HSV IgM assays cannot be used to distinguish primary from recurrent infection because reactivation can also induce the production of IgM antibody.¹⁷⁴

Local production of HSV IgG in CSF samples can be used to document HSV encephalitis in some patients, but a 2- to 4-week interval is required to demonstrate this change, and it cannot be used to guide antiviral therapy.^{285,418,423} Testing CSF for HSV IgM antibodies has no demonstrated diagnostic value.

Genetic Analysis for Molecular Epidemiology

HSV DNA from epidemiologically unrelated isolates has a specific cleavage pattern when digested by endonuclease restriction enzymes and subjected to gel electrophoresis (Fig. 158.19).⁶⁴ This restriction fragment length polymorphism (RFLP) method is primarily used for epidemiologic purposes to demonstrate relatedness among isolates during the evaluation of apparent outbreaks or nosocomial transmission events.^{64,65,166,255,460} In addition, RFLP analysis has contributed to our understanding of exogenous reinfection versus recurrence and the possibility that individuals may harbor more than one latent virus strain. This method is laborious and not typically performed in diagnostic laboratories. Precise differentiation of HSV strains requires genomic sequencing, which is performed on a research basis.

Antiviral Drug Susceptibility Testing

The persistence of lesions, emergence of new lesions, or increasing plasma viral load despite appropriate antiviral therapy is suggestive of treatment failure and should prompt laboratory evaluation of antiviral resistance. This testing may be useful to guide selection of an alternative therapy, but, unfortunately, testing is not readily available in clinical practice or even in large reference laboratories. Although resistance is uncommon in immunocompetent patients (prevalence 0.1–0.7%), immunocompromised patients, many of whom receive long-term HSV prophylaxis or treatment, are at relatively high risk for the development of resistance (prevalence 2.5–11%).³¹⁴ The gold standard method for HSV antiviral susceptibility testing is the plaque reduction assay. This phenotypic assay uses Vero cells (African green monkey kidney cells) inoculated with a standardized viral inoculum and incubated for 48 to 72 hours in the presence of serial drug concentrations and no drug controls.^{322,404,448} After incubation, the cells are fixed and stained, the number of plaques or focal areas of cytopathic effect is counted, and the concentration of drug that reduces the plaque number by 50%

FIG. 158.19 Electrophoretic separation of the DNA fragments of four herpes simplex virus (HSV) isolates by size, produced by restriction endonuclease enzyme digestion using the BamHI enzyme. Lanes 1 and 2 are two different HSV-2 clinical isolates, whereas lanes 3 and 4 are two different HSV-1 clinical isolates. The origin of the gel is at the top. (Courtesy Dr. Saul Kit, Division of Biochemical Virology, Baylor College of Medicine, Houston.)

(IC₅₀) is calculated. The plaque reduction assay has well-described breakpoint values of 2 µg/mL or greater for acyclovir and 100 µg/mL or greater for foscarnet. Other phenotypic susceptibility methods utilize a variety of techniques to measure HSV replication in culture, including dye uptake, ELISA, DNA hybridization, and PCR assay.^{243,314,412,448} Specific breakpoint values will vary based on the assay. Although laborious, phenotypic evaluation remains the primary approach to HSV susceptibility testing in clinical laboratories. Sequence analysis of the genes encoding thymidine kinase (*UL23*) and DNA polymerase (*UL30*), the targets of HSV antiviral agents acyclovir and foscarnet, have revealed a large number of resistance mutations as well as polymorphisms that do not contribute to the resistance phenotype.^{251,314,349} Genotypic susceptibility testing is primarily utilized as a research tool to understand the mechanism of antiviral resistance and is not generally performed for clinical purposes.

PROGNOSIS, COMPLICATIONS, AND SEQUELAE

Most HSV infections occurring beyond the fetal and neonatal periods cause minor morbidity but may be life threatening if brain or other internal organs are involved. The introduction of antiviral drugs that inhibit HSV replication has changed the management and outcome of these infections. Even before these drugs were available, eczema herpeticum resolved without sequelae in most cases. Despite administration of antiviral therapy, HSV encephalitis can be fatal or be associated with serious consequences ranging from moderate to extensive and permanent neurologic disability.⁴⁴³ The case-fatality rate for untreated encephalitis may be as high as 75%,⁴⁶⁴ and progressive neurologic damage may occur.^{118,163,221} In a series of PCR-diagnosed cases, a Glasgow Coma Scale score lower than 11 was associated with a poor outcome, and the youngest

cohort, those younger than 3 years, had higher morbidity and mortality rates.¹⁸⁹ Genital herpes causes significant physical and psychological morbidity. In immunocompromised patients, disseminated HSV infection can result in fatal or serious illness. HSV is one of the most common infectious causes of blindness in developed countries.

TREATMENT

HSV-1 and HSV-2 infections are treated with acyclovir or related drugs. Acyclovir is a nucleoside analog that is a competitive inhibitor of HSV DNA polymerase, and it terminates DNA chain elongation. Acyclovir is an inactive agent. Inhibition of viral DNA synthesis by blocking viral DNA polymerase and DNA chain elongation requires phosphorylation of acyclovir. HSV-1 and HSV-2 viral thymidine kinases are much more active than are mammalian cell kinases, and acyclovir becomes a specific antiviral agent in the presence of viral thymidine kinase.

Because the oral bioavailability of acyclovir is only approximately 20%, efficacy with oral administration requires high and frequent dosing. Concentrations of acyclovir achieved in CSF are approximately 50% of plasma levels. Acyclovir is excreted by glomerular filtration, so doses must be reduced in patients with impaired renal function. Acyclovir has been an exceptionally safe drug in clinical practice, but adverse reactions, including rash, nausea, vomiting, diarrhea, abdominal pain, headache, and neutropenia, can occur. Neurotoxicity may occur with an overdose, usually when the dose is not adjusted for poor renal clearance. Acyclovir also can cause acute renal insufficiency by precipitation in the renal tubules in dehydrated patients with high plasma concentrations or by rapid infusion of the drug. Valacyclovir, the L-valine ester of acyclovir, is converted to acyclovir⁴²² and has much higher bioavailability after oral administration, with plasma concentrations similar to those obtained after intravenous administration of acyclovir. Famciclovir is an oral prodrug of penciclovir⁴¹²; it also is well absorbed orally and is metabolized to the active form on absorption. The major advantage of these agents is that less frequent dosing is required than with acyclovir. HSV-1 and HSV-2 seldom are resistant to acyclovir or related drugs in the immunocompetent host (<1%). Resistance can occur in up to 10% of isolates from immunocompromised patients who receive prolonged antiviral therapy. HSV isolates resistant to acyclovir usually have mutations in the gene encoding viral thymidine kinase (*UL23*) and less often to *UL30*, which encodes for the viral target DNA polymerase enzyme. Foscarnet or, in some cases, cidofovir is an alternative for the treatment of acyclovir-resistant HSV.⁴⁴ Resistance to foscarnet and cidofovir has been reported.^{314,470}

Oral HSV Infection

Although published experience is limited, administration of oral acyclovir to children with gingivostomatitis is appropriate and can be expected to modify the duration of symptoms if it is initiated early in the clinical course.¹⁸⁴ Several small placebo-controlled trials of primary herpes gingivostomatitis in young children have been reported.^{6,11} In one study, the pain and hypersalivation resolved more quickly in acyclovir-treated patients.¹²⁵ In a larger study, symptoms resolved more rapidly with a 10-day course of oral acyclovir 600 mg/m² four times a day; differences were observed in drooling (4 vs. 8 days with placebo), gum swelling (5 vs. 7 days), speed of healing of intraoral lesions (6 vs. 8 days), appearance of new lesions (57% vs. 94%), and viral shedding in saliva (4 vs. 10 days). Therapy had no effect on the subsequent development of cold sores.¹¹ A comparison of oral acyclovir suspension, 15 mg/kg five times a day for 7 days, and placebo started within 72 hours documented that drug recipients had a shorter duration of oral lesions (median of 4 vs. 10 days [difference, 6 days; 95% confidence interval (CI), 4.0–8.0]) and earlier resolution of other symptoms, including fever (1 vs. 3 days [difference, 2 days; CI, 0.8–3.2]), extraoral lesions (0 vs. 5.5 days [difference, 5.5 days; CI, 1.3–4.7]), difficulty eating (4 vs. 7 days [difference, 3 days; CI, 1.31–4.69]), and difficulty drinking (3 vs. 6 days [difference, 3 days; CI, 1.1–4.9]).⁶ Treatment also decreased the period of viral shedding (1 vs. 5 days [difference, 4 days; CI, 2.9–5.1]). Symptomatic therapy includes antipyretics and oral hydration. The use of oral anesthetics is not recommended and has resulted in self-injury as a result of children chewing on anesthetized oral mucosa or lips.

Although the duration of symptoms is shorter with recurrences, children with frequent or severe recurrences may benefit from treatment with oral acyclovir as soon as new lesions appear. Topical acyclovir has been licensed for the treatment of recurrent oral herpes labialis based on experience in adults. However, its benefits on clinical symptoms are minimal. If treatment in children is indicated, oral acyclovir is the best option. Studies in adult patients with herpes labialis show that patient-initiated, high-dose, short-duration treatment with valacyclovir or famciclovir initiated at the onset of symptoms significantly reduces the time to healing and hastens resolution of pain and tenderness when compared with placebo.^{381,384}

Several studies have produced conflicting results regarding the use of topical acyclovir for the treatment of oral herpes recurrences. Topical acyclovir can decrease the duration of HSV shedding from 2 to 3 days with placebo treatment to 1 to 2 days,³⁸⁶ and the effect on symptoms is either none or subtle (1 less day with vesicles and a 2- to 3-day acceleration of healing). Although no controlled studies have been conducted, acyclovir therapy should be used for the treatment of rare cases of HSV esophagitis in normal hosts.¹⁴⁴

HSV Keratitis

Children with HSV keratitis should be referred for immediate evaluation by an ophthalmologist who is familiar with this illness and its progressive, sight-threatening forms and with optimal antiviral therapy.⁴⁴² The use of cycloplegic and antiinflammatory agents, which may be necessary, requires specialized experience. Topical preparations have been shown to have a beneficial effect on HSV keratitis and probably other superficial ocular HSV infections such as conjunctivitis and blepharitis.²⁵³ These preparations include idoxuridine (Stoxil), vidarabine (Vira-A), trifluridine (Viroptic), and acyclovir. Neonates with ocular involvement with HSV should also receive both a topical ophthalmic drug and parenteral acyclovir or other antiviral treatment. Orally administered acyclovir also has been used to treat dendritic keratitis, with effects that were similar to those achieved with topical acyclovir in the treatment of dendritic corneal ulceration. Several series suggest that oral acyclovir is therapeutic in patients who have stromal keratitis or keratouveitis.^{247,368} When given in conjunction with topical antiviral therapy, the response to oral acyclovir is good, even in those who had failed topical therapy.³⁶⁹ Oral therapy also is useful for prophylaxis against viral reactivation in those with stromal keratitis,⁴⁶⁶ and prophylaxis is associated with decreased recurrence of corneal disease.⁴⁷⁵

HSV Encephalitis

Intravenous acyclovir is the drug of choice for HSV encephalitis.⁴⁵² For children 3 months to 12 years of age, 10 to 15 mg/kg per dose every 8 hours is recommended. For children older than 12 years of age and for adults, 10 mg/kg per dose every 8 hours is recommended.¹⁹² Renal function and hydration status should both be monitored closely while the patient is receiving intravenous acyclovir. The recommended duration of therapy ranges from 14 to 21 days or longer and should be determined by clinical response and HSV DNA PCR levels in CSF. Neonates with any form of HSV infection, including encephalitis, should receive parenteral acyclovir until HSV DNA PCR assay of the CSF is negative. Thereafter, oral acyclovir suppressive therapy should be administered at a dose of 300 mg/m² per dose every 8 hours for 6 months, to improve neurodevelopmental outcomes and prevent skin recurrences.²¹⁴

Two well-controlled clinical studies in Sweden and the United States that compared vidarabine with acyclovir 30 mg/kg per day in three divided doses for 10 to 12 days provided evidence that acyclovir is significantly more effective than vidarabine in treating HSV encephalitis.^{375,453} In the Swedish study, the early mortality rate was 19% in the acyclovir-treated group and 50% in the vidarabine-treated group.³⁷⁵ The National Institutes of Health collaborative study⁴⁵³ generated similar data. As was observed in the earlier vidarabine studies,⁴⁶⁴ younger age and less severe neurologic signs at initiation of therapy markedly influence the outcome of HSV encephalitis treated with acyclovir. Lethargic patients have a 15% mortality rate, whereas comatose patients have a 40% mortality rate.

In addition to antiviral therapy, intensive care is required for optimizing the outcome of these patients. Fluid management for the prevention

of overhydration or underhydration is critical. Frequently, direct measurement of intracranial pressure is necessary for effective monitoring of increased pressure and treatment with diuretic agents. Anticonvulsant therapy for management of the often severe and prolonged seizures, as well as ventilatory support, usually is necessary at some time during the illness.

Genital HSV Infection

Recommended antiviral therapies for genital herpes simplex infection include acyclovir, famciclovir, and valacyclovir (Box 158.3), but acyclovir remains the best studied drug in children.^{82,112} Although topical acyclovir was the first antiviral therapy used to treat genital herpes, it has been replaced by the oral agent. Some benefit was observed with the topical drug, but it is difficult to use, and its effectiveness is limited when compared with oral acyclovir; treatment decreased the mean duration of viral shedding (4.1 vs. 7.0 days with placebo) and time to crusting of lesions (7.1 vs. 10.5 days).⁹⁹ In the treatment of recurrent genital disease, topical acyclovir generally tended to have a minor effect on the duration of viral shedding (from 1–2 days in treated patients vs. 2–3 days in placebo recipients), with little or no effect on symptoms.^{261,327} These results were not improved markedly with the immediate use of topical ointment. Early studies in which intravenous acyclovir was given to patients with primary genital HSV infection also were performed.^{98,274} When used in a placebo-controlled, double-blind study at a dose of 5 mg/kg every 8 hours for 5 days, acyclovir decreased the duration of viral shedding (2 vs. 8 to 13 days in placebo-treated patients), shortened the duration of local and systemic symptoms by 2 to 5 days, and decreased the time to healing by 7 to 12 days. Complications such as extragenital lesions or urinary retention were reduced significantly.³⁰⁷

Oral acyclovir has therapeutic effects on both primary and recurrent HSV infection in adults and should be given to adolescents with these infections. The major effect of intravenous acyclovir therapy on the first episode of genital HSV infection is seen in those who have true

BOX 158.3 Recommended Treatment Regimens for Adults and Adolescents With Genital Herpes Simplex Virus Infection

First Clinical Episode

Acyclovir 400 mg orally 3 times a day for 7–10 days
or
Acyclovir 200 mg orally 5 times a day for 7–10 days
or
Famciclovir 250 mg orally 3 times a day for 7–10 days
or
Valacyclovir 1 g orally twice a day for 7–10 days

Suppressive Therapy

Acyclovir 400 mg orally twice a day
or
Famciclovir 250 mg orally twice a day
or
Valacyclovir 500 mg orally once a day
or
Valacyclovir 1 g orally once a day

Episodic Therapy*

Acyclovir 400 mg orally 3 times a day for 5 days
or
Famciclovir 125 mg orally twice a day for 5 days
or
Valacyclovir 500 mg orally twice a day for 3 days

*Additional dosing recommendations can be found in the guidelines referenced. From Centers for Disease Control and Prevention: Sexually transmitted disease treatment guidelines 2010. *MMWR Recomm Rep.* 2010;59(RR-12);1–109.

primary disease, as opposed to those who have HSV-1 immunity and are experiencing new HSV-2 infection.³⁰⁷ The intravenous route of administration has been replaced by oral therapy with acyclovir and related agents. In either case, optimal benefit requires early intervention. In a double-blind, placebo-controlled study of patients with primary genital infection, acyclovir at a dose of 200 mg five times per day for 5 to 10 days significantly reduced viral shedding (1–6 days vs. 13–15 days with placebo), lesion formation after 48 hours (0–4% vs. 43–44%), the duration of lesions (10–12 vs. 16–21 days), and the duration and severity of symptoms.⁶³ In similar studies of adult patients with recurrent genital HSV infection, acyclovir 200 mg five times per day for 5 days decreased the duration of virus shedding (1–2 vs. 2–4 days), time to healing (5–6 vs. 6–7 days), and development of new lesions (2–10% vs. 19–25%), especially when administered early in the recurrence.²⁹³

In these short-term studies in which patients were cautioned regarding hydration, no significant side effects were observed. Furthermore, no cytogenetic effects were noted.⁹¹ Studies of virus from either placebo or acyclovir recipients showed that 4% to 15% of viruses isolated after therapy were more resistant to acyclovir, regardless of therapy.⁹² Neither oral nor intravenous acyclovir reduces the rate of recurrence when used to treat either primary or recurrent genital infection. Oral antiviral agents are appropriate for patients who have primary genital HSV infection, HSV proctitis,^{82,335} and frequent recurrent disease. Intravenous acyclovir should be reserved for patients who have severe local or disseminated disease with pneumonitis, hepatitis, or meningoencephalitis or complications such as urinary retention or aseptic meningitis syndrome.^{82,307}

In adults, valacyclovir administered two times a day was as effective as acyclovir administered five times a day in the treatment of first-episode genital herpes.¹³⁶ When compared with placebo, valacyclovir is as effective as acyclovir in suppressing HSV viral replication as measured by culture and HSV PCR assay.¹⁶² Similarly, famciclovir is efficacious in the treatment of first-episode and recurrent genital HSV infection.^{12,341}

Symptomatic therapy for HSV lesions should be directed toward reduction of local discomfort, promotion of healing, and prevention of autoinoculation and superinfection. Nonspecific creams and ointments probably delay healing and increase risk for the development of maceration and infection. Keeping lesions clean and dry probably is the most important local measure. Urinating sometimes is painful and can be made less so if done in a bathtub or sitz bath. Some experts advise Burow solution sitz baths or short compress treatments. Prolonged soaking delays healing.

Mucocutaneous HSV Infection in Immunocompromised Hosts

Acyclovir and related drugs given orally or intravenously are the agents of choice for serious mucocutaneous HSV-1 or HSV-2 infection in high-risk hosts. Early initiation of treatment provides the best outcome. Given the limited oral bioavailability of acyclovir, higher plasma concentrations can be achieved with valacyclovir or famciclovir, but clinical experience with these drugs remains limited in children. If the infection is considered potentially life threatening, intravenous acyclovir is the treatment of choice. Therapeutic responses to HSV infection in immunocompromised hosts have been difficult to study because of the variable nature of the disease. The historical experience with vidarabine demonstrated the benefits of antiviral therapy initially. In a randomized, controlled, crossover study of mucocutaneous HSV infection, vidarabine 10 mg/kg per day intravenously in a 12-hour infusion was shown to decrease pain and induce defervescence in patients older than 40 years. In none of the 85 patients in this study did visceral dissemination of HSV develop. However, these observations are of historical interest now because the drug is not available and has been replaced by acyclovir. Acyclovir ointment appears to have some minor effects on pain, viral shedding, and time to complete healing of lesions in immunocompromised persons with mild, non-life-threatening mucocutaneous HSV infection,⁴⁶¹ but oral acyclovir is more effective for mild illness.

Patients with more severe illness should receive care in a hospital setting with the intravenous preparation. Intravenous acyclovir has been analyzed extensively in immunocompromised patients with mucocutaneous HSV infection.^{143,334} When used early, acyclovir arrests the progression of infection. In several double-blind, placebo-controlled studies, acyclovir has been shown to be highly effective. It decreased the time to cessation

TABLE 158.2 Guidelines for Dosing Intervals of Acyclovir in Patients With Renal Impairment^a

Creatinine Clearance (mL/min/1.7 M ²)	Dose	Dosing Interval (H)
≥50	Normal	8
25–50	Normal	12
10–25	Normal	24
0–10	50% of normal	24

^aA dose should be administered after each dialysis session in patients undergoing hemodialysis.

of new lesions (1 vs. 3 days with placebo), time to lesion crusting (3–7 vs. 9–14 days), time to lesion healing (12–14 vs. 18–28 days), cessation of pain (4–10 vs. 7–16 days), and termination of viral shedding (3 vs. 14–17 days).⁴³³ Acyclovir administered intravenously is the most effective agent and the drug of choice for treating HSV in an immunocompromised host. The dosage is 250 mg/m² or 5 to 10 mg/kg per dose every 8 hours infused over a 1-hour period. In patients with severe disease, the dose may be doubled. The major toxic effect has been renal, with reversible obstructive nephropathy and transient rises in serum creatinine levels (5–10% of patients). Adequate hydration, keeping urine specific gravity measurements less than 1.010, usually prevents this problem. Dosage guidelines have been established in patients who have impaired renal function (Table 158.2). From 1% to 5% of patients may experience nausea and vomiting. Less commonly (1%), reversible neurologic symptoms (lethargy, agitation, tremor, disorientation, coma, transient hemiparesis) and laboratory abnormalities (abnormal EEG, increased CSF myelin basic protein) have developed in bone marrow transplant recipients. These patients usually had received interferon and CNS chemoprophylaxis for leukemia.⁴³² Other less serious problems include phlebitis (14%) and hives (5%).

Several studies have focused on the use of oral acyclovir in this patient population.³⁹⁶ The IC₅₀ of acyclovir generally is 0.1 to 0.5 µg/mL for HSV-1 and 0.5 to 2 µg/mL for HSV-2. Many studies use molar concentrations; in the case of acyclovir, the dose in micromoles divided by 4 equals the dose in micrograms per milliliter. Whereas peak serum levels with intravenous acyclovir vary from 8 to 15 µg/mL, the levels achieved with oral therapy are considerably lower (1 to 2 µg/mL). In preliminary studies of relatively small populations of immunocompromised adults, oral acyclovir at doses of 200 mg five times per day effectively promoted the healing of lesions and inhibited viral shedding.³⁹⁶ Pediatric studies have used oral doses of 600 mg/m² given four times per day.⁴⁰⁰ The relative efficacies of oral and intravenous acyclovir have not been compared in this setting. The choice of route of administration requires clinical judgment about the degree of immunosuppression, assessment for evidence of dissemination, and frequent reevaluation if oral drug is given.

Preliminary pharmacokinetic information regarding valacyclovir in immunocompromised children is available.²⁸¹ Valacyclovir was administered to 28 immunocompromised children aged 5 to 12 years in an open-label, randomized, dose-ranging study. Doses of valacyclovir administered were 250 or 500 mg twice a day or 500 mg three times a day. Pharmacokinetic evaluation has estimated that the bioavailability of oral valacyclovir is twofold to fourfold greater than that of oral acyclovir. The information provided in this study provides preliminary guidance for dosing of oral valacyclovir in children; however, more studies are needed to determine efficacy and safety in children. Recently published data regarding the pharmacokinetics of valacyclovir suspension in children suggest that valacyclovir oral suspension at doses of 10 and 20 mg/kg administered two to three times daily in children 3 months to 12 years of age produces drug levels similar to doses of 500 mg and 1000 mg caplets, respectively in adults.²¹² Pharmacokinetics of famciclovir in children are also being evaluated with a recently proposed dosing scheme that awaits formal clinical evaluation.⁴⁵

All studies of acyclovir in immunosuppressed patients have documented the propensity of recurrent lesions to reappear when therapy

is withdrawn. Whether acyclovir reduces the humoral and cellular immune responses to HSV is not certain.⁴³¹

Neonatal Herpes Simplex Virus Infection

Antiviral therapy for neonatal HSV disease significantly improves mortality rates and long-term outcomes of infected neonates. Historically, vidarabine was the first commercially available drug for the treatment of neonatal HSV disease. Placebo-controlled trials demonstrated that vidarabine at doses of 15 or 30 mg/kg per day given as a 12-hour infusion significantly reduced the mortality rate from 62% in historic cases and placebo controls to 35% in treated cases and increased the percentage of normal survivors from 19% to 43%. Results were best in infants with disseminated infection and disease localized to the CNS, with the mortality rate being reduced from 70% to 40% and the percentage of normal survivors increased from 10% to 30%. No difference was found between the 15 mg and the 30 mg dose in side effects, but the higher dose appeared to inhibit more effectively the progression of disease from skin-eye-mouth involvement to disseminated or CNS disease. None of the 49 treated patients had significant adverse clinical reactions or laboratory abnormalities attributable to the drug. On the negative side, 21% of infants progressed to more serious disease while receiving therapy and serious neurologic sequelae developed in 27% of the total. Fifteen percent of infants with disseminated or CNS disease continued to excrete HSV in the throat after 10 days of therapy.

The results of a vidarabine-acyclovir comparison trial in the treatment of neonatal herpes did not show any difference in efficacy and safety between the two drugs.⁴⁵⁴ When the results with vidarabine and vidarabine-acyclovir were combined, the mortality rate was reduced from 49% in untreated historical controls to 17% in treated patients. Normal survivors increased from 26% to 67%. Although the results in the total group of patients were encouraging, the outcome in the group of patients with disseminated disease was not: a mortality rate of 54% in treated patients versus 76% in untreated historical controls and normal development in 59% of treated survivors versus 54% of controls. Factors that predicted mortality and their relative risk were as follows: disseminated disease, 3.3; CNS disease, 5.8; semicomatose or comatose, 5.2; disseminated intravascular coagulation, 3.8; prematurity, 3.7; and pneumonitis, 3.6.⁴⁵⁵ Factors significantly associated with neurologic sequelae in survivors and their relative risk in these studies were as follows: skin-eye-mouth disease with three or more recurrent skin lesions after completion of acute therapy, 2.1; skin-eye-mouth disease caused by HSV-2, 1.4; HSV-2 infection, regardless of disease category, 4.9; CNS disease, 4.4; and seizures, 3.0. In infants with HSV disease limited to the skin, eye, or mouth, neonates with HSV-1 infection were all normal developmentally at 1 year of age as compared with 86% of those with HSV-2 infection. Among the latter infants, those with impaired neurologic outcome were significantly more likely to have had three or more skin recurrences in the first 6 months of life.

Because of greater ease of administration, intravenous acyclovir has supplanted vidarabine as the drug of choice for the treatment of neonatal HSV infection. Vidarabine no longer is available commercially. Because mortality and morbidity in neonates with HSV infection remained high using standard (30 mg/kg per day) dosing of acyclovir for 10 days, intermediate-dose (45 mg/kg per day) and high-dose (60 mg/kg per day) intravenous acyclovir for 21 days in 79 neonates was evaluated to treat neonatal HSV infection. Data were compared with those of a previous study in which all infants received standard doses of acyclovir (30 mg/kg per day) for 10 days. Overall, after stratification for disease category, the survival rate for patients treated with high-dose acyclovir was significantly higher than that for patients treated with the standard dose. Specifically, in neonates who received high-dose acyclovir, those with disseminated disease but not encephalitis had a significantly higher survival rate. The mortality rate at 24 months for patients with disseminated disease who received 21 days of high-dose acyclovir was 31%, compared with 57% for patients who received an intermediate dose for 21 days and 61% for those who received the standard dose for 10 days in the earlier study. For encephalitis, the mortality rate of infants at 24 months was 6% with high-dose acyclovir, 20% with the intermediate dose, and 19% with the standard dose. In addition, recipients of high-dose acyclovir had less morbidity than did historical control infants who

received the standard dose of acyclovir. Patients treated with high-dose acyclovir were 6.6 times as likely to have normal development at 12 months of age. Among infants with encephalitis, however, 31% of high-dose acyclovir recipients were developing normally at 12 months compared with 29% of patients treated with the standard dose. With respect to toxicity in the high-dose acyclovir recipients, 21% had a transient neutropenia that resolved either during continuation of high-dose acyclovir or after its cessation. Nephrotoxicity occurred in four (6%) infants who had disseminated disease. Because acyclovir is eliminated by the kidneys, the dose should be adjusted for renal disease. High-dose acyclovir did not impede the development of an adequate antibody response to HSV in infected infants.

These studies have led to the current recommendation for the use of intravenous acyclovir at a dose of 60 mg/kg per day for a minimum of 21 days to treat neonatal CNS and disseminated HSV disease and a minimum for 14 days for skin-eye-mouth disease.⁵ In addition, infants with ocular involvement should receive a topical ophthalmic drug (1–2% trifluridine, 1% idoxuridine, or 3% vidarabine), in addition to systemic acyclovir. Consultation with an ophthalmologist is also recommended to assist in the management of ocular HSV in the neonate, because corticosteroids and other medications may be indicated in some patients to preserve vision. All patients with HSV CNS infection should have a repeat lumbar puncture performed at the completion of acyclovir therapy to determine resolution of abnormal CSF parameters and to document whether the CSF specimen is HSV culture and/or HSV DNA PCR negative. A positive result from a CSF HSV PCR assay at the end of 21 days is an indication for continuing intravenous acyclovir therapy and, if clinically indicated, for performing repeat neuroimaging studies to evaluate the extent of CNS damage. Repeat samples of blood and CSF should be obtained weekly until HSV studies are negative.¹⁹¹

Concern has been raised that some infants may have progressive neurologic injury after acquiring neonatal herpes encephalitis. In addition, infants who have three or more skin recurrences with HSV-2 in the first 6 months of life have been shown to be at increased risk for having neurodevelopmental abnormalities at follow-up, whether as a consequence of previously undetected CNS infection or because of CNS dissemination during skin reactivation. Suppression of HSV skin reactivation by the administration of acyclovir (300 mg/m² per dose given orally three times daily) for 6 months is recommended.⁵ Oral suppression for 6 months also improves neurodevelopmental outcome in neonates with all forms of HSV infection. The infant's blood cell counts should be monitored while receiving long-term oral acyclovir therapy because documented suppressive therapy resulted in neutropenia in 50% of treated infants. In addition, emergence of acyclovir-resistant HSV isolates has been documented. Acyclovir suppression also has been used after development of HSV eye infection in which reactivation might imperil vision.

General supportive measures, such as maintenance of fluid and electrolyte balance, correction of hypoglycemia, management of disseminated intravascular coagulation and shock, control of seizures with anticonvulsants, mechanical support of the respiratory system, nutritional support, and antimicrobial therapy for complicating bacterial infections, also are critical in improving the outcome for neonates with HSV infection. Because neonates with a disseminated form of HSV with hepatitis and hepatic necrosis may have secondary peritonitis and gram-negative bacteremia or sepsis, administration of antibiotics is also recommended. In severe cases of hepatic failure associated with neonatal disseminated HSV infection, liver transplantation has been effective treatment for some infants.^{275,330}

Acyclovir-Resistant HSV Infection

Despite its widespread use, acyclovir remains an effective antiviral compound. In immunocompetent hosts, acyclovir resistance has been an unusual problem, even with prolonged courses of suppressive therapy. Mutant, thymidine kinase-negative virus strains have been recovered in 3% to 10% of patients treated with acyclovir, but acyclovir-resistant virus also can be recovered in placebo-treated patients, thus indicating that subpopulations of HSV are present in the lesions.⁹² Thymidine kinase-negative HSV recurrences in immunocompromised patients have been documented well, with demonstration of the ability of these viruses to establish latency and recur. These viral mutants are less virulent in

animal models. Patients who were culture positive for such mutants often have thymidine kinase-positive HSV isolates recovered from lesions during their next recurrence.³⁷³

Acyclovir-resistant virus occasionally has been shed by immunocompetent patients before, during, or after receiving therapy, yet it usually has not been associated with treatment failure.^{161,226,248,397} In pretreatment patients, 3.6% of isolates (31 of 870) were resistant to acyclovir (not inhibited by 3 µg/mL). A similar percentage (3.1%) of resistant isolates was recovered from 663 immunocompetent patients after administration of acyclovir therapy.⁹² An immunocompetent patient was reported who had an acyclovir-resistant virus containing an altered thymidine kinase that caused multiple recurrences of genital herpes unresponsive to acyclovir therapy.²²⁶ In another immunocompetent patient receiving prophylactic acyclovir for recurrent genital herpes and long-term prednisone therapy for chronic urticaria, recurrent genital lesions with acyclovir- and penciclovir-resistant HSV-2 developed.²²⁸ To date, these occurrences remain rare findings in the immunocompetent patient population. Acyclovir-resistant HSV has also been documented in neonates treated for HSV infection.²⁵²

Drug resistance occasionally is a problem in the acyclovir-treated immunocompromised population. Cases of acyclovir-resistant virus causing local invasive disease and, less commonly, dissemination and acyclovir-unresponsive meningoencephalitis have been reported.^{143,146,258,344} Recurrences with acyclovir-resistant HSV-1 may be encountered, as described in a child with Wiskott-Aldrich syndrome.^{348,349} Of the three mechanisms of altered sensitivity of HSV to acyclovir (absent thymidine kinase [TK¹], altered thymidine kinase [TK^A], and altered viral DNA polymerase), the TK² type is encountered in the vast majority of cases.^{92,143,146} These viruses cannot phosphorylate acyclovir and convert it to the active triphosphate. Among bone marrow transplant recipients receiving multiple courses of acyclovir, acyclovir-resistant virus was recovered from 2% of patients during initial therapy and from 9% after treatment of a second recurrence. In a tertiary care center, acyclovir-resistant, clinically significant virus was recovered from 5% of immunocompromised patients (usually after receiving acyclovir) but not from any immunocompetent hosts.¹³⁰ Illness caused by acyclovir-resistant viruses was more severe in pediatric patients and occurred more commonly in very immunocompromised patients, such as those with AIDS or those who had undergone bone marrow transplantation.¹³¹ Among bone marrow transplant recipients and patients with AIDS who were tested after receiving acyclovir therapy, 18% (105 of 582) had isolates that were acyclovir resistant.⁹² In vitro viral susceptibility of HSV has been highly associated with clinical response to acyclovir in HIV-infected patients.³⁴⁵ Acyclovir-resistant isolates are resistant to penciclovir and ganciclovir, which also require phosphorylation. Foscarnet has been used and is associated with successful clinical response and cessation of viral shedding. The most common side effects of foscarnet are nephrotoxicity (azotemia), alterations in serum calcium and phosphorus, and neutropenia, which has been observed in 10 to 25% of patients.^{202,344} Foscarnet therapy is indicated for an immunocompromised patient who has HSV infection unresponsive to acyclovir. Viral susceptibility testing may aid in clinical management.^{314,346}

In patients receiving chronic or multiple courses of foscarnet, foscarnet-resistant HSV isolates (IC₅₀ >100 µg/mL) have been recovered from lesions failing to respond to foscarnet.^{345,346} Of note, these lesions often responded to acyclovir, alone or in combination with foscarnet.³⁴⁶ Perhaps the mutation in DNA polymerase responsible for foscarnet resistance was in an area not related to acyclovir activity. Other experimental strategies used to treat acyclovir-resistant viruses have included high-dose, continuous-infusion acyclovir (1.5 to 2.0 mg/kg per hour) or intravenous cidofovir,^{61,130,237,377} although recent cases of cidofovir-resistant isolates have been reported.⁴⁷⁰ In the case of acyclovir- and foscarnet-resistant viruses, topical 3-hydroxy-2-phosphonomethoxypropyl cytosine (HPMPC or cidofovir) or a combination of topical trifluorothymidine and interferon-α^{42,343,348} has been used successfully in patients with chronic mucocutaneous lesions.

Prevention and Infection Control

Because HSV infection is ubiquitous in the human population and intermittent asymptomatic shedding is extremely common, preventing

transmission of HSV is difficult. By diminishing the passage of infectious HSV-2, condoms offer moderate protection and should be recommended routinely.^{266,436} Circumcised males are also less likely to acquire HSV-2 infection compared with uncircumcised controls.⁴¹⁴

HSV is sensitive to heat and lipid solvents, so the use of antiseptics, soap and hot water, or chlorine decreases the risk for transfer of virus in settings such as the home, spas, pools, wrestling meets, and hospitals. In addition, appropriate use of gloves and other personal protective wear, by all health care personnel who come in contact with potentially infected body secretions or rashes should decrease the acquisition and health care-associated transmission of HSV. Health care workers with an active herpetic whitlow should wear gloves and not have direct patient care responsibilities for neonates and immunocompromised patients.⁵ Health care workers with active oral herpes lesions should practice good hygiene and precautions, and reassignment to non-patient care areas should be made on an individual basis. Health care providers should wear gloves and wash carefully before and after contact with respiratory or genital tract secretions. Parents and caretakers of infants with eczema or severe diaper rash should be especially careful to avoid making direct or indirect contact of this altered skin with an active HSV lesion. Burn patients should be protected against exposure to or direct contact with personnel or visitors who have active HSV lesions. Immunosuppressed patients with evidence of HSV infection usually are experiencing reactivation of latent virus. Primary HSV infections in immunosuppressed persons, as in neonates, may be especially severe, and protecting these susceptible patients against exposure to HSV lesions is important. Wrestlers and rugby players who have exposed skin lesions caused by HSV should be excluded from competition.

The major approaches to the prevention of neonatal herpes involve interruption of transmission from sites of HSV infection and disease at the time of delivery and postnatally from a variety of potential sources. Because in utero transplacental congenital infection occurs so infrequently and predicting the occurrence of congenital infection during pregnancy is not possible, no standard recommendations for prophylaxis are available.

Cesarean delivery within 4 hours of rupture of fetal membranes in a mother with active genital herpes at the time of delivery is recommended to reduce the risk for natal infection. Because serial vaginal cultures taken during the latter stages of pregnancy have failed to predict shedding at the time of delivery, such monitoring is not recommended. Cesarean delivery is recommended only for women with active vesicular or ulcerative lesions at the time of delivery.⁵ Cesarean delivery is not always 100% protective, even if the membranes are intact. Between 1.2% and 3% and, in one study, up to 33% of neonates with HSV infection are delivered by cesarean delivery. The cost-effectiveness of performing a cesarean delivery in women with recurrent lesions at delivery has been questioned by some experts, but it remains the current recommendation in the United States. Multiple clinical trials have shown that administration of prophylactic acyclovir and valacyclovir beginning at 36 weeks' gestation reduces the risk for clinically apparent HSV genital vesicles and ulcers at delivery, reduces the risk for HSV viral shedding at delivery, and also reduces the incidence of cesarean delivery. However, although the hope is that the risk for HSV disease in the neonate also would be reduced, in none of these studies was sufficient power or evidence available to determine the effect of peripartum prophylaxis on the incidence of neonatal HSV. No adverse effects have been seen in infants exposed to maternal acyclovir during pregnancy. Because fetal scalp electrode monitor, forceps, and maneuvers that might cause a break in the infant's skin during delivery appear to increase the risk for acquisition of neonatal HSV, they should be used only with clear indication and a careful assessment of the risk-to-benefit ratio.

The results of antenatal genital HSV cultures from pregnant women with a history of genital herpes do not predict the infant's risk for exposure to HSV at delivery. Because 60% to 80% of mothers of infants with neonatal herpes are asymptomatic or have unrecognized infection, the optimal approach may be to perform a screening test to identify women shedding or likely to shed HSV at the time of delivery. Although HSV rapid antigen-detection tests continue to be developed commercially, their sensitivity in *asymptomatic* women still is only 60% to 75%. Screening of pregnant women for non-type-specific HSV antibody

would be confounded by the presence of HSV-1 antibody, which is present in 60% to 80% of the population. The presence of HSV-1 antibody probably represents oral herpes, which poses little risk to the neonate. Although type-specific antibody assays are available to identify pregnant women infected with HSV-2, such an approach would miss women with genital HSV-1 infection or those with asymptomatic primary HSV-2 infection near the time of delivery before antibody is detectable. Its use has been recommended in identifying discordant couples, that is, women with no history of having genital HSV infection but whose sexual partner has had previous infection, so barrier precautions may be used before delivery to decrease the chance of development of a maternal primary infection that poses a greater risk to her infant. Culturing the genital tract of women at the time of vaginal delivery would identify infants exposed to HSV and allow anticipatory management. However, because genital HSV infection rates are only 0.1% to 0.4%, this approach likely would not be practical or cost effective for *all* women. Culturing of *selected* women at delivery could focus on (1) positive or partner-discordant HSV-2 serologic tests, (2) those women with a history of genital herpes in themselves or their sexual partners, (3) those women with a history of another sexually transmitted disease or multiple sexual partners, and (4) mothers with a history of maternal fever in labor. However, routine or selective serologic screening, although recommended by some experts, is not currently a standard recommendation, and further investigation is required to determine whether screening of pregnant women to prevent neonatal herpes is beneficial, practical, and cost effective.

No studies have been conducted on the optimal management of asymptomatic infants exposed to maternal HSV infection at delivery, although guidelines on maternal and neonatal evaluation and prophylactic or anticipatory antiviral therapy are available.²¹¹ A recently published algorithm for the evaluation of asymptomatic neonates following vaginal or cesarean delivery to women with active genital herpes lesions recommends the following approach:

1. Obstetricians who note a visible lesion should obtain a swab for HSV culture and HSV PCR and determine maternal history of genital HSV preceding pregnancy.
2. If there is a positive maternal history of prior genital HSV, HSV surface cultures and PCR, and blood PCR should be obtained from the asymptomatic infant at 24 hours of age. If the mother has recurrent infection, the risk of neonatal disease is probably less than 3% to 5%. Acyclovir does not need to be initiated if the infant remains asymptomatic. If the laboratory studies from the infant are negative, then the family is educated regarding signs and symptoms of neonatal HSV disease and the infant is followed closely. If any of the infant testing is positive, then further evaluation is performed and intravenous acyclovir is initiated.
3. If there is no maternal history of prior genital HSV, then it is recommended that type-specific serology for HSV-1 and HSV-2 antibodies be sent from the mother. At 24 hours of age, HSV surface cultures and HSV PCR, HSV blood PCR, CSF studies, and serum ALT should be obtained from the infant. Intravenous acyclovir at 60 mg/kg per dose in three divided doses is then initiated pending results of maternal serology. The duration of treatment is dependent on whether maternal lesion culture and PCR are positive and whether maternal serology reflects first episode primary, first episode nonprimary, or recurrent infection. If maternal serology is consistent with primary or first episode nonprimary infection at delivery, the neonatal infection rate may be as high as 30% to 50%.

It is recommended that this management algorithm be used only in facilities where access to PCR and type-specific serologic testing is readily available and turnaround time for test results is reasonably short. In addition, evaluation and treatment is indicated in any infant before 24 hours of age if signs and symptoms of HSV disease are present. Immediate evaluation and treatment may be considered if infant is preterm (≤ 37 weeks' gestation) or there was prolonged rupture of membranes (> 4 –6 hours). Situations that increase the risk for neonatal transmission despite maternal recurrent disease include prematurity, the use of a scalp electrode monitor, or skin lacerations. All infants should be monitored closely for any clinical evidence of HSV infection. Any positive culture or the occurrence of signs or symptoms suggesting

HSV infection in the neonate suggests that a full virologic evaluation, including blood and CSF analysis for HSV by PCR, should be performed and antiviral therapy initiated. Antiviral therapy also should be administered to neonates with positive HSV cultures of mucosal sites, and these neonates should not be assessed as being merely colonized, because all require intravenous acyclovir therapy.⁵ Breast-feeding is contraindicated only if the mother has a vesicular lesion on her breast. Physicians also have recommended that circumcision be delayed for 1 month in infants at highest risk for transmission.

Prevention of postnatally acquired neonatal infection needs to take into account the potential sources of HSV: (1) maternal oral herpes or breast lesions; (2) household member, such as father or sibling, or other close contact, such as grandparent or caretaker, with oral herpes or herpetic gingivostomatitis; and (3) health care–associated transmission from other infected infants or health care workers. Transmission to the neonate from family members with oral herpes lesions can be interrupted by education, avoidance of kissing and nuzzling of the neonate if they have oral herpes ulcers or history of “cold sores,” and avoidance of touching the neonate if they have a herpetic skin lesion or whitlow, as well as common-sense personal hygiene, including hand washing. Health care–associated transmission can be reduced by contact isolation and hospital infection control measures, as well as universal precautions and good hand washing techniques. Personnel with herpetic whitlow should not have direct patient care responsibilities until the lesion has healed. Infants with HSV infection should be placed in contact isolation for the duration of the illness.⁵ The median duration of viral shedding from skin vesicles and mucosal sites in infants receiving acyclovir is 5 to 8 days. Asymptomatic but high-risk infants born to mothers with herpes at delivery also should be in contact isolation; alternatively, they may room in with the mother in a private room.

Immunoprophylaxis and Chemoprophylaxis

The development of vaccines is a long-term objective that has significant potential to ameliorate the disease burden associated with HSV-1 and HSV-2.¹⁵ However, to date, attempts to create effective HSV vaccines have met with limited success.^{39,272,338,389} In one early report, a vaccine containing the recombinant glycoprotein D of HSV-2 (gD₂) was used in patients who had established recurrent genital herpes infections, and vaccine recipients had a third fewer genital herpes recurrences than those experienced by placebo recipients during the study year.³⁹³ However, experience with the use of recombinant vaccines to prevent primary HSV infections has yielded mixed results. Recombinant HSV-2 gD₂ and gB₂ have been demonstrated to induce high humoral and cell-mediated immune responses in seronegative and seropositive recipients.²⁴¹ Some vaccines may protect women who have no HSV immunity at baseline.³⁸⁹ In a study of discordant couples, an HSV-2 gD₂ subunit vaccine with alum and monophosphoryl lipid adjuvant was approximately 73% effective in preventing symptomatic genital HSV-2 disease in women who were seronegative for both HSV-1 and HSV-2.³⁹¹ However, when the same vaccine was given to 8323 women who were negative for antibodies to HSV-1 and HSV-2 in a randomized double-blind efficacy field trial, the vaccine was not efficacious, presumably owing to differences in the populations studied.³⁹ These studies illustrate that high levels of neutralizing antibody do not guarantee protection against infection. Other vaccine types in early stages of development include disabled infectious single-cycle virus vaccines, live genetically attenuated vaccines, and naked DNA.^{389,463} No adequate controlled trials of high-dose intravenous immune globulin as an intervention to suppress frequently recurring genital herpes have been reported, and this method is not likely to be effective because infected patients have high titers of HSV-specific antibodies.²⁶⁷

Intramuscular human interferon- α administered before and after surgery on the trigeminal nerve root significantly decreased the incidence of HSV shedding and clinical reactivation.³⁰⁶ In similar studies, interferon had no significant effect on HSV shedding or reactivation in renal transplant patients.⁸⁷

Intravenous acyclovir has been shown to prevent reactivation of HSV almost completely in immunosuppressed patients receiving a bone marrow transplant or antileukemic chemotherapy.³⁵⁴ In patients with bone marrow transplants, intravenous therapy is begun at the onset of

immunosuppression and continued through the immediate transplant period, and then therapy is switched to oral acyclovir for several months.¹⁵¹ Oral acyclovir administered chronically markedly suppressed recurrence in immunodeficient patients.⁴⁰⁵ The use of prophylactic acyclovir is indicated in HSV-seropositive, immunosuppressed pediatric patients. Long-term use of suppressive prophylactic acyclovir appears to prevent the emergence of drug-resistant HSV disease in hematopoietic stem cell transplant recipients.^{112,132}

Oral acyclovir 200 mg two to five times per day administered chronically can prevent reactivation of genital HSV nearly completely in patients with frequent recurrences. Recurrences decreased by 50% to 70%, and the time to recurrence changed from 14 to 25 days in patients receiving placebo to 100 to 125 days in those receiving acyclovir.^{121,397} Breakthrough recurrences tended to be mild and to have less viral shedding and rarely were caused by acyclovir-resistant virus. When acyclovir was discontinued (after 12 to 15 weeks of administration), HSV recurrences reverted to the pretreatment frequency. Higher doses of acyclovir suppressed recurrences in patients experiencing a “breakthrough” with more conventional doses. In patients receiving therapy for 5 years, the number of recurrences declined from the first year (1.7) to the fifth year (0.8). From 20% to 25% of patients are recurrence free for 4 to 5 years.¹⁵² After prophylactic therapy ended, suppressive therapy no longer was warranted in some patients because of longer periods between recurrences.^{137,394} Patients who had resistant virus exhibited re-isolation of acyclovir-sensitive virus. Thus, acyclovir suppressed recurrences without eliminating latent virus. One study has reported that acyclovir does not seem to change the rate of asymptomatic viral shedding.³⁹⁵ A subsequent study demonstrated that acyclovir 400 mg twice a day resulted in a 95% reduction in subclinical viral shedding when compared with placebo in women with genital herpes.⁴³⁹ Side effects of chronic acyclovir therapy include an increase in mean corpuscular volume and hemoglobin concentration without anemia or megaloblastic changes, neutropenia and asthenia, and mild gastrointestinal upset.³⁹⁷ Valacyclovir and famciclovir also can be used to suppress frequently recurring genital herpes effectively, and they suppress both symptomatic and asymptomatic HSV shedding.^{111,162,340,438} Both drugs are more expensive than is acyclovir. The decision of whether to use episodic or suppressive therapy for individuals with recurrent genital HSV infection depends on the frequency of recurrences. Those with a recent primary infection and frequent recurrences may prefer long-term suppressive therapy. If episodic therapy is used, it should be initiated as soon as symptoms begin. Oral herpetic recurrences were prevented in skiers given a brief course of acyclovir during their ski trip.³⁸³

Chronic antiviral suppressive therapy with valacyclovir reduced genital HSV transmission in heterosexual HSV-2-discordant couples in one study.¹⁰⁰ Once-daily suppressive therapy with valacyclovir or placebo was given to the HSV-2-seropositive partner. Acquisition of HSV-2 occurred in four of 743 susceptible partners given valacyclovir and 16 of 741 susceptible partners given placebo (hazard ratio, 0.52). HSV was identified in genital secretions 2.9% of days in source partners receiving valacyclovir and 10.8% of days in placebo recipients. Use of condoms and abstinence during symptomatic outbreaks still are recommended. Use of HSV type-specific serologic testing to identify HSV-seropositive individuals and disclosure of HSV status, in combination with condom use, risk reduction counseling, and long-term suppressive antiviral therapy have the potential to control the spread of HSV-2 infection.^{155,435} The US Preventive Services Task Force Recommendation Statement from 2016 however recommended against routine serologic screening for genital HSV-2 infection in asymptomatic adolescents and young adults because serologic screening results in many false positive results which may cause psychosocial harm and distress, and antiviral prophylaxis has not been shown in randomized clinical trials to prevent transmission of HSV-2.^{135,424} The potential utility of antiviral therapy against herpes simplex however is being evaluated as a strategy for prevention of HIV infection.^{76,77}

The role of antiviral therapy during pregnancy to prevent neonatal HSV infection is undergoing evaluation for safety and efficacy. In one randomized, blinded trial, women with recurrent genital HSV received either acyclovir, 400 mg three times a day, or placebo from 36 weeks' gestation until delivery. Genital lesions were present at delivery in 14%

of women receiving placebo and 5% of women taking acyclovir ($P = .08$). A significant decrease in HSV culture and PCR positivity was noted in the acyclovir group near the time of delivery. No significant difference in delivery by cesarean section was found between the groups. Suppressive acyclovir treatment decreased but did not eliminate genital lesions or HSV viral detection at delivery.⁴⁴⁵ Another randomized, placebo-controlled study evaluated the effect of daily valacyclovir suppression initiated at 36 weeks' gestation. Women receiving valacyclovir had fewer recurrences of genital HSV; however, valacyclovir suppression did not decrease the number of women who had viral shedding or lesions near delivery. A limited sample size may have contributed to failure to observe a significant difference in groups treated with drug versus placebo.¹⁰ Neonatal HSV infection may still occur after maternal acyclovir suppression, as illustrated by a recently published case series.³¹³

Experience with acyclovir prophylaxis for reactivation of HSV in children is limited. Prophylactic oral acyclovir 30 to 60 mg/kg per day in three to five doses for 1 week has been shown to decrease seroconversion effectively and to eradicate symptomatic cases of HSV gingivostomatitis in a nursery setting in which outbreaks of primary HSV infection were occurring.²³³ Suppression, at doses of 300 mg/m² three times daily, has been effective in infants with frequent recurrences of HSV after neonatal HSV infection and has been safe, although prolonged use has been associated with reversible neutropenia. To date, prolonged suppressive therapy in adults has not resulted in serious side effects^{137,152,394} or an increase in the problem of drug-resistant HSV in a healthy host.

Cytomegalovirus

159

Gail J. Harrison

Cytomegalovirus (CMV) is a ubiquitous agent that commonly infects persons of all ages from all parts of the world and from all socioeconomic and cultural backgrounds. Although most CMV infections are asymptomatic, certain patient groups are at risk for acquiring serious, even life-threatening illness. Discerning which role CMV is playing in a particular patient requires a thorough understanding of the epidemiology, virology, and pathophysiology of the virus and can be difficult, even for the most experienced clinicians.

HISTORY

The recorded history of CMV probably began when Ribbert⁴²¹ described in 1881 and then reported in 1904 “protozoan-like cells” in the organs of an infant who died of presumed congenital syphilis. In 1921, Goodpasture and Talbot²⁰² hypothesized that these swollen cells, or “cytomegalia,” were host cells that had been injured by a virus. During the first half of the 20th century, CMV was recognizable only by the pathologic changes that it produced in infected cells; because these cells frequently were seen in the salivary glands of animals and humans, CMV originally was called the “salivary gland virus.”

In 1956, human CMV was isolated in tissue culture by independent investigators Rowe and colleagues,⁴³⁵ Smith,⁴⁶¹ and Weller and associates.⁵³⁰ Because several human and animal viruses subsequently were found to replicate in salivary glands, the descriptive name *cytomegalovirus* was proposed by Weller in 1960. The ability to cultivate CMV in tissue culture led to the development of serologic techniques, which in the 1960s and 1970s resulted in many important clinical and epidemiologic observations. For example, CMV was found to infect people of all ages throughout the world. By 1962, CMV was established as a significant pathogen of the fetus and neonate that was capable of producing a spectrum of clinical manifestations and neurologic sequelae.⁵²⁹ In 1966, Kaariainen and colleagues²⁵⁹ presented evidence supporting CMV as a cause of posttransfusion mononucleosis syndrome.

The molecular biology of the virus was explored during the 1970s and 1980s and continues to be studied by many investigators. In addition, during the 1970s and 1980s, CMV emerged as a major cause of morbidity and mortality in immunosuppressed patients, especially those who underwent organ or marrow transplantation or who had acquired immunodeficiency syndrome (AIDS) or a congenital primary combined immune deficiency syndrome.

In 1976, the first clinical trial of the live, attenuated CMV vaccine Towne 125 was reported; since then, more than 500 renal allograft recipients, as well as healthy young men and women, have received the vaccine under investigational protocols.^{177,388} In addition, research on a glycoprotein B subunit vaccine based on one of the glycoproteins of the virus began in the 1980s; and in the 1990s and the early part of the 21st century, other recombinant vaccines were developed and tested in human volunteers. Beginning in 2000, clinical trials with other vaccines, such as DNA vaccines, alphavirus replicon particles, and live, attenuated

viral vaccines using chimeric viruses constructed from Towne strain and Toledo strain of CMV, were conducted.^{13,490}

However, after decades of research, a successful CMV vaccine remains elusive. In 1999, the Institute of Medicine of the National Academy of Sciences assigned a high priority for a vaccine to prevent CMV infection, an action that was quickly endorsed in 2000 by the National Vaccine Advisory Committee, based on the lifetime costs to society and the human suffering associated with CMV disease in neonates and immunocompromised individuals.^{29,267}

Attempts by clinicians to treat CMV disease began in the late 1960s and early 1970s,¹⁶⁷ and now CMV infection is a treatable disease; several specific and effective antiviral agents, including ganciclovir (licensed in 1989), foscarnet (licensed in 1991), and cidofovir (licensed in 1996), are available to clinicians to treat seriously ill patients.⁸³ In addition, valganciclovir, an oral form of ganciclovir available in tablets and solution, has facilitated long-term, outpatient treatment for CMV disease and CMV prophylaxis in immunocompromised pediatric patients and infants with congenital CMV infection.^{273,380,510}

In 2000 to 2017, immunomodulating agents, such as CMV hyperimmune globulin and adoptive immunotherapies using CMV-specific cytotoxic T lymphocytes, have been evaluated in clinical trials as adjuncts to available antiviral therapies to prevent or treat CMV infection and disease in immunocompromised transplant recipients and in pregnant women to reduce risk for CMV transmission to the fetus.^{193,257,408,419}

A resurgence of awareness of CMV from public health officials and the lay community began in 2004, providing hope that prevention and treatment of CMV disease may become a priority for research, education, and public health policy.⁸⁸ In 2013, the first groundbreaking CMV public health legislation was passed in Utah. This law, “Rule R398-4. Cytomegalovirus Public Education and Testing” [H.B. 81 (2013 General Session) UCA 26-10-10] directed the Utah Department of Health to create a public education program to inform pregnant women and women who may become pregnant about the occurrence of CMV, the transmission of CMV, the birth defects that are caused by CMV, methods of CMV diagnosis, and available preventative measures. This law also directs medical practitioners to test infants who fail newborn screening for congenital CMV and inform the parents about the possible birth defects caused by CMV.^{142,549}

Since the Utah law passed, at least 6 states have enacted CMV laws that create public education programs for pregnant women or women who may become pregnant, or create targeted newborn testing programs for congenital CMV for newborns who fail their newborn hearing screens; 6 additional states have CMV legislation proposed, and an additional 12 states have CMV legislation in discussion.⁵⁴⁹ In addition, evidence shows that universal newborn screening for congenital CMV may be cost effective, and the debate continues as more research unfolds about adding congenital CMV to the recommended uniform screening panel for newborn screening.¹⁹²

VIROLOGY

CMV is a member of the Herpesviridae family of DNA viruses. This family contains many important human pathogens and is subdivided into three subfamilies: (1) Alphaherpesvirinae, fast-growing, cytolytic viruses that are latent in neurons and include herpes simplex virus (HSV) types 1 and 2 and varicella-zoster virus (VZV); (2) Betaherpesvirinae, slow-growing, cytomegalic viruses that contain the CMVs; and (3) Gammaherpesvirinae, herpesviruses that preferentially grow in lymphocytes and sometimes transform them into malignant states; this subfamily includes Epstein-Barr virus and human herpesviruses 6, 7, and 8.

CMV is the largest member of Herpesviridae. The genome is double-stranded DNA 240 kb in size (150×106 daltons; guanine + cytosine [G + C] content, 58%), and it has a unique long sequence and a unique short sequence, both of which are bounded by repetitive sequences that are inverted relative to each other. The genome, therefore, can assume four isomeric forms. The viral particle has a 110-nm icosahedral capsid composed of 162 capsomeres. The entire virion is enclosed by a lipid envelope, which yields a final diameter of approximately 200 nm.⁴⁸⁴

Replication of CMV is slow compared with that of HSV. Whereas it takes herpes simplex only 4 to 8 hours to produce infectious progeny virus, CMV requires at least 24 hours. The CMV genome is transcribed slowly in a regulated sequence; on the basis of the appearance of different classes of CMV-specific proteins, the replicative cycle can be divided into three periods: immediate-early, early, and late. The immediate-early period is defined as the first 4 hours after infection occurs. During this period, specific segments of the DNA genome undergo restricted transcription and certain regulatory proteins are produced that allow the virus to take control of host-cell macromolecular synthesis. The early period of replication begins after the immediate-early phase and persists for almost 20 hours. This period is characterized by replication of viral DNA, synthesis of infected cell proteins, and production of progeny virus. The late period usually is considered to occur 24 hours after infection develops. During this period, the structural components of the virus are produced, and infectious virus is released from the cell. Monoclonal antibodies against the various immediate-early, early, and late proteins produced by CMV have been used as rapid viral diagnostic tools. Cytomegalovirus entry into fibroblasts differs from entry into epithelial cells. CMV also spreads cell to cell and can induce syncytia. This cell-to-cell spread of CMV is sensitive to antibody inhibition in epithelial cells but not fibroblasts.¹²⁵

CMV has no distinct serotypes. However, strain relatedness or differences can be determined by molecular analysis of viral DNA. Restriction enzyme analysis of DNA extracted from CMV isolates that are linked epidemiologically (e.g., serial isolates from the same person, mother-infant pairs, or family members experiencing temporally related CMV infections) shows identical or similar DNA fragment mapping patterns. This technique or modifications of this technique have been applied to the epidemiology of CMV in a variety of patients, such as transplant recipients, congenitally infected infants, and patients whose CMV was transmitted from person to person in hospitals, child care centers, and residences. Polymerase chain reaction (PCR) methodology has determined CMV genotypes exist, by showing differences in the a sequence, major immediate-early, glycoprotein B (gB or UL55), H (gH or UL75), N (gN or UL73), and UL144 regions of the viral genome.* The four gB genotypes (gB1, gB2, gB3, gB4) have been characterized, and although all genotypes cause congenital and acquired infections, studies suggest that adverse outcomes after CMV infection may be linked to infection with a specific gB genotype, but none has been conclusive. Infection with the CMV gB3 genotype appears to be associated more commonly with fatal infections in bone marrow transplant recipients and hearing loss in congenitally infected neonates, and CMV gB2 and gB4 genotypes appear to be more often fatal in patients with AIDS, in some studies.^{42,190,404,548,555} Some studies have suggested neonates with gN-4 genotype may have higher risk for sequelae, whereas others have not confirmed this association.^{239,383,384} Mixed gB genotype infections in transplant recipients may be associated with higher viral loads and delayed viral clearance.³¹⁴

Pregnant women, neonates with congenital CMV infection, healthy toddlers, and immunocompromised patients may also harbor more than one CMV genotype (gB, gH, or gN) and may have different genotypes in different compartments of the body.^{141,213,335,350,434}

EPIDEMIOLOGY

Seroepidemiologic studies have shown that infection with CMV occurs commonly in all parts of the world and usually is inapparent.^{26,54,278,513,519,565,525} However, the burden of CMV infection and severe disease may be increasing in certain high-risk groups, such as neonates and premature infants and older children and adults with immune deficiencies as well as transplant recipients.^{386,452,492} The incidence of CMV infection does not appear to be seasonal. However, the prevalence of CMV immunoglobulin G (IgG) antibody is influenced by many factors, including the age, geographic location, cultural and socioeconomic status, race or ethnicity, and child-rearing practices of the group. For example, in developed countries such as the United Kingdom and the United States, the prevalence of CMV antibody is 40% to 60% in adult populations of middle to upper socioeconomic status and more than 80% in lower socioeconomic status groups.^{210,478,564} CMV seroprevalence in the United States also may differ by race and ethnicity, with reports of 51% of non-Hispanic white individuals being CMV seropositive compared with 76% of non-Hispanic black individuals and 82% of Hispanic or Mexican Americans.^{117,148,481} In contrast, in developing countries, 80% of children acquire CMV by the time they reach 3 years of age, and almost all persons have been infected by adulthood.^{19,30,523} In countries with high HIV prevalence, CMV remains a common cofactor and an important pathogen in disease.⁵⁴ Studies on the age-related prevalence of infection with CMV in the United States suggest three periods of increased incidence of acquisition: early childhood, adolescence, and the childbearing years.^{19,532,563}

Pregnancy

Between 45% and 100% of women of childbearing age will be CMV seropositive, depending on age, race, ethnicity, and geographic location.^{92,295,405,406,525} Seroprevalence of CMV in women of childbearing age is higher usually in developing countries than in Europe or North America. In one study of US women of childbearing age, a higher CMV seroprevalence was associated with higher parity, with higher number of live births, younger age at first sexual intercourse, higher number of lifetime sexual partners, race/ethnicity of Hispanic origin, poverty index, and lower level of education.²⁹⁵ Annual seroconversion rates among CMV-seronegative pregnant women vary between 1% and 7%, with an average of 2.3%.^{241,254} Certain groups of women may be at higher risk for primary CMV infections. For example, women who work in child care centers have higher annualized seroconversion rates of 8% to 20%.⁵ Women who have a toddler who attends child care and is actively excreting CMV at the time have been observed to have a 45% annualized seroconversion rate.³⁷⁴ Although most CMV infections in pregnancy are asymptomatic, up to 50% of maternal CMV infections may have nonspecific clinical symptoms and only will be detected with specific serologic testing.³⁴¹ The risk for intrauterine transmission of CMV infection from mother to fetus during pregnancy appears to vary with type of maternal infection.^{304,313} Maternal CMV infection that is either primary or recurrent during pregnancy can result in an infant who is infected congenitally with CMV. However, the rate of intrauterine infection with recurrent infection in the mother is less than 1%, whereas transmission to the fetus occurs in 32% to 50% of mothers who are infected primarily with CMV during pregnancy.^{266,478} Naturally occurring immunity to CMV infection reduces the risk for congenital CMV infection in future pregnancies by at least 69%.¹⁸⁵ Symptoms and sequelae are also much more likely to occur in infants congenitally infected as a result of the mother's primary infection during pregnancy than in infants congenitally infected from a recurrent maternal infection.²²¹ However, even though symptoms are more likely in neonates congenitally infected as a result of a maternal primary infection, congenitally infected neonates from maternal recurrent CMV infections, resulting from reactivation of endogenous strain or reinfection with a new strain, may also experience long-term sequelae, including hearing loss and neurologic

BOX 159.1 Sources of Cytomegalovirus Infection

Congenital (acquired before birth from maternal source)

Perinatal (acquired at or around time of birth from maternal sources)

- Breast milk
- Cervicovaginal secretions

Postnatal (acquired after birth from nonmaternal sources)

- Blood product transfusions
- Organ transplantation
- Stem cell transplantation
- Person-to-person transmission (close contact such as sharing food or drink, kissing, sexual contact)

disease.¹⁰⁵ In one study from Finland, symptomatic congenital CMV infections were more commonly due to maternal nonprimary infection than proven maternal primary infections with CMV, and resulted in significant morbidity to the newborn.³⁹⁸

Congenital Infection

Approximately 1% of all neonates are born congenitally infected with CMV; ranges of 0.18% to 6.1% have been reported, varying between countries and the social demographics of the population.^{266,313,560} Congenital infections arise from maternal source through vertical transmission (Box 159.1). Birth prevalence of congenital CMV infection is higher in developing countries than in Europe and North America in most studies because of the higher maternal CMV serologic seroprevalence ranging from 84% to 100% in developing countries.^{293,525} An estimated 30,000 to 40,000 neonates with congenital CMV infection are born annually in the United States.^{47,99,437} Less than 20% (estimated 5–15% in most studies) of children with congenital CMV infection show obvious clinical signs at birth, resulting in an estimated 8000 to 10,000 children annually in the United States who have long-term neurologic and sensory sequelae of hearing and vision disorders from congenital CMV disease.^{516,296} Although most neonates congenitally infected with CMV do not have symptoms, up to 20% of apparently symptom-free neonates with congenital CMV have hearing loss by 18 years of age—either congenital hearing loss or later onset, progressive sensorineural hearing loss.²⁹²

Perinatal Infection

CMV can be transmitted perinatally from a mother to her infant³⁸⁶ (see Box 159.1). The virus can be shed in the CMV-seropositive mother's cervicovaginal secretions, urine, saliva, and breast milk. The most common and most efficient routes of perinatal transmission are ingestion or aspiration of cervicovaginal secretions at the time of delivery or ingestion of fresh breast milk after delivery. CMV-seropositive mothers, especially mothers with high levels of CMV IgG antibody, frequently shed CMV in their breast milk; and as many as 53% of children who are breast-fed with milk that contains infectious virus or CMV DNA can become infected with CMV.^{158,252,360,520} These infections usually are benign in full-term infants but may be extremely serious in preterm, very-low-birth-weight neonates, associated with prolonged hospitalization, bronchopulmonary dysplasia, and mortality rates of 9%.^{265,291,318,518} In addition, as many as 57% of neonates whose mothers shed CMV at or around the time of delivery become infected with CMV.⁴²⁰

Postnatal Infection in Childhood

Children not congenitally or perinatally infected with CMV may be infected during the toddler or preschool years through person-to-person transmission³⁸⁶ (see Box 159.1). The acquisition of CMV by children between 1 and 3 years of age is influenced by home exposure to the virus, by the socioeconomic status or country of origin of the family, and by group child care exposure.⁹¹ Weller and Hanshaw⁵²⁹ suggested that the child-rearing practices in Sweden, where group child care was common practice, accounted for the relatively high prevalence of CMV

infection in Swedish children compared with children in the United States and Great Britain, where child care centers were not common at that time.

Pass and colleagues³⁷⁰ first reported the prevalence of CMV in child care centers in the United States in 1982. They found that 51% of children who attended a child care center in Alabama excreted CMV in their saliva or urine. In this study, the prevalence of CMV excretion varied with age; 83% of children aged 13 to 24 months shed virus, as opposed to only 9% of children younger than 1 year old. Pass and colleagues concluded that the high prevalence of CMV infection probably was due to horizontal spread between the children in child care. Subsequent studies have confirmed a high prevalence of CMV excretion in children in child care centers across the United States. Overall prevalence rates of 11% to 57% have been observed in many other studies in the United States and other countries, with the highest prevalence of active CMV infection (29–78%) found in children 1 to 3 years of age.^{4,255,340,354,355} Child care homes may have lower prevalence of CMV excretion in children (8–15%); however, CMV seroconversion in home child care providers appears similar to that of child care providers in larger centers.^{43,370,373,372} Children who attend child care centers also shed high titers of virus (up to 10⁵ median tissue culture infective dose per milliliter), with a mean duration of viral shedding of 13 months in urine and 7 months in saliva.³³⁹ This prolonged, generally asymptomatic shedding of large quantities of virus, coupled with mobility and the less than hygienic daily habits notorious in toddlers, no doubt facilitates the transmission of CMV in child care centers.

Several studies support the idea that the high prevalence of CMV infection in young children who attend child care centers is due to horizontal transmission; these studies used molecular fingerprinting techniques to show that infected children in contact with each other shed strains of CMV with similar or identical restriction enzyme banding patterns and that predominant strains of CMV appeared to circulate during a given period in a given child care center.^{5,4,238} Reinfection with a genetically different strain of CMV also has been observed and may be important in child-to-child transmission of CMV in the child care center environment.⁹ The importance of horizontal spread of CMV has been shown in special care centers for mentally retarded children as well.⁴⁵⁵ CMV also has been isolated from plastic toys and from the hands of child care center workers.^{165,238,370}

CMV-infected children may transmit the virus to the child care center workers.^{5,7} In addition, children who attend child care centers may transmit CMV to their CMV-seronegative parents. In one study of parents of children who attended one of three child care centers in Alabama, 14 of 67 parents (21%) whose children attended group child care seroconverted, compared with none of 31 parents whose children were cared for at home.³⁷⁴ Excretion of CMV by the child clearly was a key risk factor for parental seroconversion because none of the seroconversions occurred in parents whose children attended the child care center but did not shed CMV. Moreover, this study revealed a strong trend toward a greater risk for acquiring CMV infection (seroconversion rate, 45%) in the parents of children 18 months or younger. Additional evidence implicating young children who attend child care centers as a source of CMV infection for their parents was provided by a study in Virginia child care centers, in which the parents of children in child care shed CMV strains identical to the strains shed by their children.⁶ Furthermore, CMV strains from child care settings, when transmitted from toddlers to their pregnant mothers, may be the source of congenital infection.³⁴⁰

Whereas infancy, toddlerhood, and early childhood probably are the most rapid periods of acquisition of CMV, seroprevalence of CMV IgG antibody between 1 and 5 years of age has been estimated at 20% (range, 14–28%).²⁹⁴ Annual seroconversion rates of 3% to 6.2% have been observed in older children aged 3 to 10 years in the United States and other countries, thus reflecting an age-related plateau in the acquisition of CMV. One identified risk factor for the acquisition of CMV infection in a school-aged child has been recent or active CMV infection in a family member.^{117,140,148,481,482,563}

Infection in Adolescents

In support of these early findings, a seroepidemiologic study of CMV infection in sexually active adolescent girls found a strong association

between indicators of sexual activity and serologic evidence of CMV infection and concluded that sexual activity is an important risk factor for the acquisition of CMV infection in adolescent girls.^{103,468} Early cross-sectional epidemiologic studies of CMV implied that a gradual increase in CMV antibody prevalence occurs during the teenage years, and this period of rapid acquisition was attributed to the intimate physical contact that commonly occurs during the teenage years.^{19,428} However, these studies were conducted primarily in lower socioeconomic groups. In a seroepidemiologic study of several groups in Houston, Texas, on the acquisition of CMV infection in late childhood and adolescence, the prevalence of antibody increased with age in subjects of nonwhite races, as it did according to previous studies, but the prevalence of antibody in white subjects did not increase with age.⁵³²

In one recent study, however, of sexually active African American adolescents, CMV infection as measured by CMV IgG seroprevalence was not associated with sexual activity (34% in sexually active adolescents compared with 21% in sexually inactive adolescents).¹⁸⁷

Vertical transmission of CMV acquired during the teenage years may result in congenital infection with CMV in infants born to teenage mothers. In 1984, Kumar and colleagues²⁸⁰ studied primary CMV infection in more than 3000 pregnant adolescents in Ohio. They found that 57% were CMV seropositive, that 1% of susceptible pregnant adolescents acquired CMV, and that the risk for intrauterine transmission was 50% if primary CMV infection occurred during pregnancy. Information provided by the National Congenital Cytomegalovirus Disease Registry and the National Center for Health Statistics suggests that adolescents who are pregnant actually may be at higher risk than are older mothers for giving birth to an infant with congenital CMV disease because 34% of mothers who give birth to an infant with congenital CMV disease are younger than 20 years old; however, this age group represents only 16% of the mothers giving birth in the United States.^{132,243}

Intrafamilial Transmission

CMV also can be transmitted within the family setting. Evidence for intrafamilial transmission of CMV has been provided in the form of case reports, seroepidemiologic studies, and accounts in which molecular analysis of CMV strains was used to trace the transmission of CMV in family members or extended family members with temporally related CMV infections. In most studies, the index case was a child; when a CMV-infected child entered a household, attack rates were 47% to 53%.^{494,502,556}

Three patterns of intrafamilial transmission have been observed: transmission between siblings, transmission between parents, and transmission between children and parents. Additional support for the intrafamilial transmission of CMV has been provided by published studies in which molecular analysis was performed on CMV isolates from family members or extended family members who experienced temporally related CMV infections. In each of these studies, restriction enzyme analysis of viral DNA from CMV isolates in family members showed that the strain of CMV was the same within each family.^{156,375,476,556} New molecular techniques based on PCR amplification of a hypervariable region of the CMV genome also have corroborated the observation that genetically similar strains of CMV can be transmitted between family members over the course of time.⁴⁶⁹

Sexual Transmission

CMV also appears to be transmitted by heterosexual and homosexual contact. The evidence to support sexual transmission is anecdotal, virologic, serologic, and molecular and, taken together, suggests that sexual transmission of CMV is important in certain groups. However, because the virus is shed in saliva, cervicovaginal secretions, and semen, which form of intimate contact results in transmission between sex partners is unclear.^{135,290,420}

Several observations support the idea that CMV can be transmitted sexually. For example, CMV antibody prevalence increases with age; CMV antibody is more prevalent in sexually active women than in celibate women; CMV antibody is associated with indices of sexual activity, such as recent infection with *Chlamydia trachomatis* or *Neisseria gonorrhoeae*; and a strikingly high annual incidence (37%) of primary CMV infection has been observed in young women with a recent first

sexual experience.^{104,116,130,184,256,468,482,539} In addition, in a longitudinal study of the site-specific shedding of CMV in human immunodeficiency virus (HIV)–seropositive homosexual and bisexual men, CMV was cultured from semen more frequently than from other body sites or fluids.⁴²³ Moreover, molecular analysis of viral DNA has shown strains of CMV isolated from sex partners to be identical in most cases analyzed.^{135,223}

Infection of the genital tract can recur by reactivation of an endogenous strain or by reinfection with an exogenous or different strain of CMV.⁴⁶⁸ The consequences of such reinfections are unknown but may have important implications for transmission, especially if a CMV vaccine is used to control congenital CMV disease in the future. Sexual debut and recent sexual activity significantly influence CMV seroprevalence among women of childbearing age. In addition, engaging in sexual activity within 2 years of delivery of an infant adds increased risk for delivering a congenitally infected infant. Because sexual activity appears to influence CMV seroprevalence and congenital CMV infection rates in some groups, strategies to reduce sexual transmission of CMV may be important.^{184,482}

Nosocomial Health Care–Related Transmission

CMV can be transmitted in the hospital setting by transfusion of blood products, by bone marrow and organ transplantation, and, rarely, by person-to-person transmission (see Box 159.1). Despite numerous studies that have used serologic, virologic, and molecular epidemiologic techniques, transmission of CMV from a CMV-infected patient to a health care worker has not been documented.^{10,38,44,75,137,157,236} Therefore, even though health care workers are exposed to CMV-infected patients, their risk for acquiring CMV appears to be no greater than that of the general population. In addition, unlike homes and child care centers, hospitals routinely perform rigorous infection-control procedures, including universal precautions, which probably accounts for the relatively low risk for acquiring CMV as well as other infections in the hospital setting. However, infant-to-infant transmission has been shown to occur, albeit infrequently, in crowded hospital units with a high prevalence of CMV excretion in patients.^{137,472} CMV also can survive on plastic surfaces and has been cultured from inanimate objects in contact with CMV-infected patients in the hospital setting.^{137,472}

Blood products are a well-established source of CMV infection, and donor-to-recipient transmission of CMV has been documented by restriction enzyme analysis of viral DNA.⁵⁰¹ Posttransfusion CMV mononucleosis can be seen in adults who receive large volumes of fresh whole blood.²⁵⁹ In addition, 15% to 17% of CMV-seronegative neonates who receive blood products from CMV-seropositive donors acquire CMV.^{556,557} Posttransfusion CMV infection in neonates, especially premature infants, can cause a syndrome of shock, lymphocytosis, and pneumonitis; CMV infection also appears to hasten the progression to bronchopulmonary dysplasia in these patients.^{442,557}

CMV apparently is transmitted in the residual leukocytes found in whole blood, packed red blood cells, and platelet fractions as well as by pure leukocyte transfusions. The risk for development of posttransfusion CMV infection is approximately 3% per unit transfused, and the risk for symptomatic infection is much higher in CMV-seronegative recipients than in CMV-seropositive recipients.

Extremely low-birth-weight infants in the neonatal intensive care unit have a risk for acquiring CMV infection when fed fresh or refrigerated breast milk from CMV-seropositive donors, and they may develop serious illness associated with the infection. CMV infection through breast milk may be reduced, but not eliminated, in these vulnerable neonates by feeding freeze-thawed breast milk, and likely can be prevented through pasteurization of breast milk.⁵⁶¹

Immunosuppressed Patients

Primary and reactivation infections, as well as reinfection with CMV, occur commonly in children receiving anticancer chemotherapy,²²² in children who are solid organ and marrow transplant recipients, and in infants with primary immune deficiency syndromes that involve T-cell or natural killer (NK)-cell dysfunction, severe combined immunodeficiency (SCID), or acquired immune deficiency from HIV infection or AIDS.^{222,521} The health care burden of severe CMV disease appears

to be increasing in these special pediatric patient groups.⁴⁵² Active infection with CMV occurs in almost all organ and marrow transplant recipients and usually is manifested clinically and virologically 30 to 90 days after transplantation. Rarely, CMV retinitis can occur years after a patient has undergone transplantation and generally is associated with chronic CMV viremia.¹⁷³ CMV can be transmitted to the recipient by the transplanted organ, by transfused blood products, and, theoretically, also by intimate contact with persons actively infected with CMV.

Infections with CMV are primary when they occur in CMV-seronegative recipients who receive transplants or blood products from CMV-seropositive donors. Recipients who are CMV seropositive before undergoing transplantation can experience reactivation of their own endogenous strain of CMV. In addition, CMV-seropositive transplant recipients may be superinfected by strains of CMV present in the donor organ.¹⁰⁹ In fact, in one study of renal transplant recipients in the United Kingdom, proven superinfection with the donor's strain of CMV occurred more frequently than did proven reactivation of the recipient's strain of virus.²¹⁵ Although reactivation, reinfection, and primary CMV infection all can produce symptoms in immunosuppressed transplant recipients, primary CMV infections are much more likely to be severe and even fatal.³⁹⁴

The type of transplant also appears to influence the type of CMV disease expressed. For example, the most severe and lethal form of CMV interstitial pneumonitis is seen in bone marrow transplant recipients, especially those experiencing a graft-versus-host reaction. CMV pneumonia also is a common occurrence after heart, lung, or renal transplantation, and severe CMV hepatitis is a special problem after liver transplantation.¹⁸

The iatrogenic immunosuppression essential for graft maintenance probably is responsible for the common occurrence of reactivation infection after transplantation, as well as the increased incidence of severe and symptomatic infection seen after primary CMV infection in transplant recipients. Cytotoxic drugs such as cyclophosphamide and azathioprine, in addition to corticosteroids, have been associated with reactivation of latent CMV infection, and the addition of antilymphocyte globulin to an immunosuppressive regimen can increase the morbidity of CMV infections.³⁷⁶ The use of cyclosporine as the primary immunosuppressive agent, even in conjunction with corticosteroids, does not appear to reduce the risk for acquiring CMV infection compared with a regimen of azathioprine and corticosteroids; however, it may decrease the incidence of severe, symptomatic CMV disease in some transplant recipients.¹⁵⁴ The use of OKT3 to treat rejection in certain transplant patients increases the risk for dissemination in those with primary CMV infection.⁴⁵⁸

The frequency and morbidity of CMV infection in patients with malignant neoplasms are not as high as in patients who have undergone marrow and organ transplantation; however, the use of chemotherapy, especially for leukemia, is associated with significant CMV disease, particularly pneumonitis and persistent fever with viral dissemination. CMV-seropositive patients receiving immunosuppressive therapy for connective tissue disease also can have significant reactivation infection with CMV.¹⁴⁹

The progressive and profound immunosuppression in adults and children with AIDS also is associated with CMV infection and disease. Although the source of CMV infection in adults with AIDS most likely is heterosexual or homosexual contact, sources of CMV infection in young children with AIDS have not been determined. It is likely, however, that many of these infections are acquired from the mother, either congenitally or perinatally. Infants infected perinatally with HIV who also acquire CMV congenitally appear to be at significant risk for experiencing rapid progression of disease in the first 18 months of life, as well as debilitating neurologic disease.^{150,279,451} Patients with AIDS also may be infected with multiple strains of CMV.^{153,473}

Infants with primary immune deficiency syndromes involving T-cell or NK-cell function may have persistent CMV infection and progressive, life-threatening CMV disease. They often will have very high levels of CMV DNA levels by quantitative PCR in their blood or plasma, and present with hepatosplenomegaly, pneumonitis, colitis, retinitis, meningitis, thrombocytopenia, or elevated aminotransferase levels.⁴⁹³ Because prompt diagnosis and management of possible underlying immune

FIG. 159.1 Typical cytomegalic inclusion cells seen in lung tissue obtained by open-lung biopsy from a bone marrow transplant recipient with fatal cytomegalovirus pneumonitis (x640). (Courtesy Dr. Milton J. Finegold, Department of Pathology, Texas Children's Hospital, Houston.)

disorder and specific antiviral therapy against CMV are important in these patients, most centers will screen newborns with SCID for evidence of active CMV infection.³³⁰

PATHOLOGY, PATHOGENESIS, AND IMMUNITY

CMV infection causes characteristic type A Cowdry intranuclear inclusions and massive enlargement of the affected cells (Fig. 159.1). It is this property of "cytomegaly" from which CMV acquired its name. The cytomegalic cells (25–40 μm in diameter) are two to four times larger than normal cells, and the nucleus usually is more than 10 μm in diameter. The intranuclear inclusion also is large (up to 10 μm in diameter) and is surrounded by an intranuclear halo and then the nuclear membrane, which gives a characteristic "owl's eye" appearance. Basophilic, granular, intracytoplasmic inclusions (2–4 μm in diameter) also may be present in cells that have intranuclear inclusions. These large cells represent productive virus infection, and both the nuclear and cytoplasmic inclusions contain viral nucleocapsids and express virus-specific antigens.²³⁰ These cytomegalic cells frequently are associated with epithelial cells, and their presence generally indicates a productive and symptomatic infection with CMV. Cells also may be infected latently with CMV. These cells may express virus-specific antigen and contain viral nucleic acid without producing typical cytomegaly or a cytopathic effect. The significance of these cells must be considered carefully within the clinical context of the patient.

With severe, disseminated CMV disease, involvement can be seen in virtually all organ systems. The salivary glands frequently are infected in both symptomatic and asymptomatic infections, and the ductal epithelium usually is the site of pathologic involvement. The kidneys also are infected frequently in both symptomatic and asymptomatic CMV infection. In the kidneys, cytomegalic cells are most pronounced in the proximal tubules and interstitial cellular infiltrates, and even immune complex deposits can be seen in the glomeruli.

CMV infection often causes prolonged viremia, but it rarely results in significant renal dysfunction. Virions of CMV shed in urine have a reversible block to epithelial cell entry and may be highly resistant to antibody neutralization.¹²⁴ In the lungs, cytomegalic cells are seen in alveolar and bronchial epithelium and are associated with mononuclear cell inflammation. Pulmonary alveolar macrophages also may express viral antigen and contain CMV DNA. The brain parenchyma can be involved, and a variety of pathologic processes can be observed and include sensorineural hearing loss. Other organs that can be infected or diseased with CMV include the liver, pancreas, adrenals, eyes, lymph nodes, heart, skin, bone, male and female genital tracts, esophagus, stomach, intestine, and placenta.

Infections with CMV can be latent and nonproductive, productive yet asymptomatic, or productive and symptomatic. Therefore determination of whether a patient is "sick with CMV" or "sick from CMV"

sometimes is difficult. Viral strain differences have not been shown to date to influence pathogenicity. However, immune responses, including maturity of the immune response, appear to be a major factor in virulence of the infection because CMV disease occurs more frequently in fetuses, premature neonates, transplant recipients, and patients with AIDS than in older healthy infants, children, and adults with acquired CMV infection.

The cell-mediated immune response, both specific and nonspecific, is thought to be important in host defense against CMV. The nonspecific immune mechanisms of NK cells and interferon production occur soon after the development of CMV infection, when early antigens are being produced and before infectious virus is released from the cell. The generation of cytotoxic T cells against CMV early antigens probably is the most important specific host immune response to CMV, and patients who are defective in this T-cell response are at high risk for acquiring serious CMV disease.²¹¹

Clinical and laboratory evidence also supports the concept of CMV as an immunosuppressive agent. The proliferative response of T cells to stimulation with mitogens and CMV antigen is suppressed in patients with CMV mononucleosis, and immunosuppressed patients with active CMV disease frequently have other opportunistic infections.⁴²² In addition, CMV pneumonitis in bone marrow transplant recipients has been hypothesized to result from host cell-mediated events produced in response to chronic viral replication.⁵⁶⁶ Homology between certain CMV proteins and class I and class II major histocompatibility complex products has been observed. This “molecular mimicry” implies that the severe tissue destruction seen in CMV pneumonitis may be partly an autoimmune phenomenon in these patients.

Humoral immunity, on the other hand, although contributory, does not appear to be the key factor in the host's defense against CMV infection. For example, the fetus can be infected by intrauterine transmission as a result of reactivation of CMV infection in a woman who is CMV seropositive before pregnancy, and infants frequently are infected perinatally from infected cervicovaginal secretions or breast milk in the presence of passive maternal antibody.⁴⁷⁸ In addition, CMV-seropositive transplant recipients can be reinfected with a new strain of CMV from the donor organ, and viremia and viremia occur in transplant recipients despite high titers of neutralizing antibody against the specific strain of CMV.^{109,110} The presence of CMV antibody, therefore, should be considered a marker of previous or current infection with the virus rather than a measure of immunity per se.

Although humoral immunity does not appear to prevent infection with CMV, it does appear to lessen the severity of associated symptoms. Infants congenitally infected with CMV as a result of reactivation of infection in their mother almost always are asymptomatic, whereas perinatally infected infants rarely have significant symptoms. Primary infections in transplant recipients are more likely to be symptomatic than is reinfection or reactivation. One hypothesis regarding how CMV eludes host humoral defenses is that the virus binds to the host protein β_2 -microglobulin and masks the antigenic determinants that are important for neutralization by antibody.³²¹

CLINICAL MANIFESTATIONS

Fetal and Congenital Infections

The fetus with in utero CMV infection may show ultrasonographic abnormalities, including signs of abnormal somatic or head growth, enlarged liver or spleen, echogenic bowel patterns, and hepatic calcifications, as well as biologic findings such as fetal thrombocytopenia and lymphopenia and elevated liver enzymes and elevated CMV-specific IgM antibody levels. In addition, cerebral fetal ultrasonography may show enlarged ventricles in the fetal brain, intracranial calcifications, or microcephaly or mimic a Dandy-Walker malformation in severe cases.^{35,217,307}

Annually, 30,000 to 40,000 infants are born with congenital CMV infection, and they may be symptomatic or asymptomatic at birth (Box 159.2). Of these infants, as many as 10% have severe, classical “cytomegalic inclusion disease,” characterized by intrauterine growth retardation, jaundice, hepatosplenomegaly, thrombocytopenia with petechiae and purpura, pneumonia, and severe central nervous system

BOX 159.2 Categories of Congenital Cytomegalovirus (CMV) Infection

Asymptomatic at Birth

Asymptomatic with normal hearing at birth

Asymptomatic with congenital sensorineural hearing loss (unilateral or bilateral) at birth

Asymptomatic with normal hearing at birth, with later-onset sensorineural hearing loss

Symptomatic at Birth

Classic “cytomegalic inclusion disease”

Symptomatic congenital CMV infection

Primary neurophenotype congenital CMV infection

FIG. 159.2 Congenital CMV, virologically confirmed on day 1 of life, with primary neurophenotype presentation including developmental brain malformation compatible with fetal brain disruption or fetal brain arrest syndrome. (A) Computed tomography scan with unenhanced noncontrast and (B) magnetic resonance image of brain of newborn showing severe simplification of the supratentorial gyral pattern with diffuse polymicrogyria, multiple punctate areas of periventricular calcifications, prominence of the ventricles, and cerebral volume loss. Also present on imaging was mild atrophy of the brainstem and left cerebellar hemisphere, and an abnormal corpus callosum, with a decreased craniofacial ratio compatible with the clinical finding of microcephaly. Diagnosis was suspected prenatally, when routine anatomy scan at 20 weeks' gestation showed abnormalities in the fetus and maternal serologies showed evidence of a primary cytomegalovirus infection. The baby was born at term, 38 weeks' gestation, and had profound microcephaly (head circumference, 29.5 cm), overlapping sutures, and scalp rugae. As an infant, the patient later exhibited seizures, strabismus, sensorineural hearing loss, cortical vision impairment, cerebral palsy, and severe global developmental delay.

(CNS) damage with microcephaly, intracerebral calcifications, chorioretinitis, and sensorineural hearing loss²⁹⁶ (Box 159.3). Another 5% have atypical involvement, such as ventriculomegaly, periventricular leukomalacia, periventricular cystic malformations with or without calcifications, polymicrogyria, neuronal migration abnormalities, cerebral thrombosis, strabismus, optic atrophy, long bone osteitis characterized by fine vertical metaphyseal striations, isolated and transient thrombocytopenia and petechiae, cutaneous vasculitis, hemolytic anemia, ascites, chronic hepatitis, and intrahepatic cholestatic disease.^{20,32,114,176,250,354}

Newborns with congenital CMV infection may also exhibit a primary neurophenotype, presenting with microcephaly, neonatal seizures, and abnormal brain imaging, without the somatic manifestations of classic congenital CMV disease in other organs. Fetal brain disruption sequence (FBDS), also associated with congenital Zika virus syndrome and genetic disorders, can be seen in rare cases associated with congenital CMV disease of the CNS (Fig. 159.2). Brain involvement in these other asymptomatic infants includes polymicrogyria and other cortical maldevelopment syndromes and migration disorders of the developing brain, and neurologic sequelae are common (Fig. 159.3). As many as

BOX 159.3 Clinical, Laboratory, and Brain Imaging Findings Associated With Symptomatic Congenital Cytomegalovirus (CMV) Infection

Clinical Findings

Small for gestational age
 Jaundice at birth
 Petechiae or purpura
 Hepatosplenomegaly
 Ascites
 Myocarditis
 Enterocolitis
 Lethargy and poor sucking ability
 Hypotonia
 Viral sepsis syndrome
 Hemophagocytic lymphohistiocytosis syndrome
 Pneumonitis
 Chorioretinitis, optic atrophy, cortical vision impairments, delayed vision maturation
 Seizures
 Hemolytic anemia
 Microcephaly
 Fetal brain sequence disruption or arrest syndrome (extreme microcephaly, overriding sutures, flattened cranium, and scalp rugae)
 Sensorineural hearing loss (unilateral or bilateral)

Laboratory Findings

Thrombocytopenia
 Elevated liver transaminases
 Elevated direct and indirect serum bilirubin
 Hemolytic anemia
 Neutropenia
 Lymphopenia
 Lymphocytosis
 Leukemoid reaction
 Elevated CSF protein levels
 CMV detected by polymerase chain reaction or culture in saliva, urine, blood, or CSF
 CMV immunoglobulin M antibody elevation

Brain Imaging Findings

Microcephaly
 Intracranial calcifications (periventricular most common location)
 Ventriculomegaly
 Ventricular septations or adhesions
 Periventricular leukomalacia
 Periventricular cystic abnormalities/malformations
 Lenticulostriate vasculopathy
 Migration abnormalities (unilateral or bilateral polymicrogyria, pachygyria, lissencephaly)
 Vasculitis or stroke
 Cerebral atrophy
 Dysgenesis of corpus callosum
 Cerebellar hypoplasia
 Fetal brain sequence disruption or arrest syndrome

CSF, Cerebrospinal fluid.

90% of these infants who are symptomatic at birth with classic somatic manifestations also later may have neurologic sequelae, vision loss, or progressive deafness. However, the range of severity of these sequelae appears to be broad, and severity may be predicted by head circumference, prenatal fetal and postnatal neonatal head ultrasound, and computed tomography (CT) and magnetic resonance imaging (MRI) findings in

FIG. 159.3 Congenital cytomegalovirus (CMV) with primary neuropenotype presenting with microcephaly, left hemiparesis, left sensorineural hearing loss, and seizures. Magnetic resonance imaging of brain shows abnormal right cerebral hemisphere, smaller than the left, with cortical polymicrogyria of the right frontal, temporal, and parietal lobes; volume loss of cerebral white matter; enlargement of the right lateral ventricle; and small right brainstem. The cerebellum and corpus callosum appeared normal. Newborn was born premature at 36 weeks' gestation, with mild microcephaly. Diagnosis of congenital CMV was not suspected until later in infancy, when microcephaly was apparent, and was confirmed retrospectively by detection of CMV DNA by polymerase chain reaction on newborn screening dried blood spots, retrieved with parental permission from the state newborn screening laboratory.

the fetus prenatally and in the newborn at birth.^{33,70,89,352,362} In addition, CMV viremia and high levels of CMV DNA by PCR analysis in the blood or plasma in congenitally infected neonates is associated with symptomatic disease and hearing loss at birth. Development of hearing loss in newborns with asymptomatic congenital CMV infection has been associated with CMV DNAemia levels higher than 17,000 copies/mL.¹⁷⁹ These studies suggest that the level of virus contributes to disease severity in some newborns with congenital CMV.^{69,74}

The differential diagnosis of symptomatic congenital CMV disease includes congenital Zika virus syndrome, congenital toxoplasmosis, congenital HSV infection, congenital syphilis, congenital rubella syndrome, congenital infection with lymphocytic choriomeningitis virus, and congenital HIV infection (Box 159.4). In addition, noninfectious causes, such as genetic disorders, metabolic disease, and maternal exposure to drugs and toxins, should be considered.

Most infants who are infected congenitally with CMV are asymptomatic at birth (see Box 159.2). However, 10% to 17% of these infants later may have unilateral or bilateral deafness at birth or develop later differences in higher-level auditory function.^{118,478,538} Progressive or late-onset hearing loss also may occur in these infants, with up to 20% of children born with asymptomatic congenital CMV infection by 18 years of age having hearing loss, and with 2% of them with severe hearing loss requiring cochlear implant devices.²⁹² It is therefore likely that universal neonatal hearing screening programs, even if paired with targeted testing for congenital CMV infection, will miss rather than detect many of these children.^{181,292,353} Small retinal lesions may occur as well in children born with asymptomatic congenital CMV infection, but they are rarely sight threatening.^{114,253} Earlier studies suggested that developmental problems may occur in asymptotically infected children, but more recent studies suggest that cognitive outcome, at least as measured by intelligence quotients and achievement testing, appears to be normal compared with uninfected children.²⁶³

BOX 159.4 Differential Diagnosis of Symptomatic Congenital Cytomegalovirus Infection, Including Isolated Neuropenotype

Other Congenital and Neonatal Viral Infections

Zika virus
Herpes simplex virus
Rubella virus
HIV
Lymphocytic choriomeningitis virus
Hepatitis A, B, or C
Epstein-Barr virus (rare)
Enterovirus
Adenovirus
Congenital toxoplasmosis
Neonatal bacterial sepsis

Genetic and Metabolic Disorders

Tuberous sclerosis
Sturge-Weber syndrome
Galactosemia
Urea cycle deficiencies
Organic acidemias
Lysosomal storage disorders
Peroxisomal disorders

In Utero Toxin or Drug Exposure

Fetal alcohol syndrome
Cocaine and other substance abuse
Isotretinoin (oral)

Other Conditions

Biliary atresia
 α_1 -Antitrypsin deficiency
Ischemia
Venous thrombosis
Hemophagocytic lymphohistiocytosis syndrome

Very-low-birth-weight infants who are infected congenitally with CMV may experience pulmonary and systemic deterioration temporally associated with corticosteroid therapy.⁵⁰⁶

Neonates and infants younger than 6 months with persistently high levels of CMV viremia or high levels of CMV DNA by PCR analysis in the blood or plasma, or infants who have significant rebound of their CMV DNA levels after antiviral treatment, may have a primary immune disorder of T-cell function, such as SCID, or a disorder of NK-cell function. Prompt diagnosis and management of the underlying immune disorder, as well as specific antiviral therapy against CMV, are important in these patients.

Perinatal Infections

Perinatally acquired infections in healthy infants usually manifest when the child is between 4 and 16 weeks of age, but most such infections are asymptomatic. However, as many as one third of infants exposed to CMV perinatally may have signs and symptoms of disease associated with CMV infection, most often self-limited lymphadenopathy, hepatosplenomegaly, hepatitis, or pneumonitis.²⁸² Perinatally acquired infection with CMV also can cause a viral, sepsis-like syndrome or severe, protracted pneumonitis that has been associated with the development of bronchopulmonary dysplasia in premature infants.^{318,442} A limited number of studies suggest that these infections, however, do not appear to cause neurodevelopmental sequelae or deafness.²⁸³ Infants with primary immune deficiency of T-cell or NK-cell function, or AIDS from perinatally acquired HIV infection, who acquire CMV perinatally may have CMV viremia, high levels of CMV DNA by PCR analysis in

blood or plasma, and associated hepatosplenomegaly, thrombocytopenia, viral sepsis, pneumonia, retinitis, meningitis, or colitis. Prompt diagnosis of an underlying primary immune disorder, as well as antiviral therapy, is life-saving management in these patients. The differential diagnosis includes other perinatally acquired infections, such as *Chlamydia* pneumonitis, hepatitis B virus infection, and infection with HIV, as well as postnatally acquired infections with enteroviruses, adenovirus, and a variety of bacterial pathogens.

Mononucleosis Syndrome

CMV-induced mononucleosis occurs as a primary infection in both immunocompetent and immunosuppressed persons, in pregnant women, and, occasionally, as a reactivation infection in immunosuppressed patients.³⁰⁴ It can result from person-to-person transmission of the virus as well as from transmission by blood products or by organ or marrow transplantation. Although originally described in adults and most often occurring in patients between 20 and 40 years of age, it also can be seen in adolescents, children, and even infants.^{312,368} Typical CMV-induced mononucleosis is characterized by fever and strikingly severe malaise of 1 to 4 weeks' duration, peripheral lymphocytosis with atypical lymphocytes, and mildly elevated liver enzymes. In some patients, headache, myalgia, and abdominal pain with diarrhea are prominent symptoms. In premature infants with transfusion-acquired CMV mononucleosis, prominent manifestations include shock, hepatosplenomegaly, pneumonitis, thrombocytopenia, and renal failure.⁴⁷² In contrast to Epstein-Barr virus-induced mononucleosis, CMV-induced mononucleosis rarely causes pharyngitis, tonsillitis, or significant splenomegaly, and it does not result in production of heterophil antibodies.^{115,237} However, like Epstein-Barr virus-induced mononucleosis, it can be associated with morbilliform rash after administration of ampicillin, elevated erythrocyte sedimentation rate, polyclonal hypergammaglobulinemia, and production of other antibodies such as rheumatoid factor, cold agglutinins, and antinuclear antibodies. Complications rarely occur but include interstitial pneumonitis, myocarditis, pericarditis, hemolytic anemia, thrombocytopenia with or without petechiae or purpura, hemophagocytic syndrome, arthralgias and arthritis, maculopapular rashes, adrenal insufficiency, splenic infarction, ulcerative colitis and proctitis, Guillain-Barré syndrome, and meningoencephalitis.^{102,115,127,172,237,276,277,303} Severe, icteric hepatitis and granulomatous hepatitis also can occur, but hepatic necrosis and liver failure caused by CMV have not been documented convincingly in normal hosts.^{67,115,237,277,415}

The differential diagnosis of CMV-induced mononucleosis includes mononucleosis induced by other viruses such as Epstein-Barr virus, hepatitis A or B virus, and HIV. In addition, acquired toxoplasmosis can produce a mononucleosis syndrome in healthy persons.

Interstitial Pneumonitis

CMV is a major cause of interstitial pneumonia in both adults and children who are immunosuppressed because of congenital primary immunodeficiency of T-cell or NK-cell function, AIDS, organ or marrow transplantation, or malignant disease. In recipients of bone marrow transplants, CMV accounts for 17% to 70% of cases of interstitial pneumonitis in adult patients but only 10% of cases in patients younger than 21 years.^{528,529} Pneumonia also can occur in apparently immunocompetent young infants with perinatally acquired CMV infection and in healthy children, adolescents, and adults with CMV-induced mononucleosis.^{269,282,477,534} Whereas the pneumonia in immunocompetent hosts almost always is benign and self-limited, CMV pneumonia in immunosuppressed patients is a serious, often fatal illness, especially in bone marrow transplant recipients, who have a mortality rate of up to 90%. It also can be particularly troublesome after pediatric heart and lung transplantation.³⁵¹ CMV pneumonitis usually occurs 1 to 3 months after the patient has undergone transplantation and begins with symptoms of fever and a dry, nonproductive cough. It then can progress during the course of 1 to 2 weeks to dyspnea, retractions, wheezing, and hypoxia, which require ventilatory support. It may occur as the only disease manifestation or be part of a disseminated CMV infection. The radiographic appearance of CMV pneumonia usually is diffuse, interstitial infiltrates, but peribronchial infiltrates with hyperinflation and nodular pulmonary infiltrates also have been described

FIG. 159.4 Chest radiograph of a bone marrow transplant recipient with rapidly fatal cytomegalovirus pneumonitis. An open-lung biopsy specimen showed numerous cytomegalic inclusion cells, exhibited cytomegalovirus early antigens by immunoperoxidase staining, and grew cytomegalovirus after inoculation into tissue culture.

(Fig. 159.4).^{269,496} Unusual central peribronchovascular patterns with organizing pneumonia that results in bronchiectasis and chronic lung damage have also been reported with CMV pneumonia in patients who received T-cell-depleted allogeneic stem cell transplantation.¹²³ Coinfection with other pathogens, especially gram-negative enteric bacteria and fungal pathogens in transplant recipients and in patients with *Pneumocystis jiroveci* infection and AIDS, can occur.⁵²⁴ A quantitative assessment of CMV DNA viral load in bronchoalveolar lavage (BAL) specimens may be helpful in providing circumstantial evidence that CMV pneumonitis is present.²⁴⁰

Congenitally infected infants also may be born with CMV pneumonitis, which often is sufficiently severe to require ventilatory support and usually is part of a multisystemic CMV disease process. Very low-birth-weight infants who are infected congenitally with CMV may experience CMV pneumonitis in temporal association with corticosteroid therapy.⁵⁰⁶

The differential diagnosis of CMV pneumonitis in immunocompromised patients, including neonates, is extensive. It includes infection with other viruses, such as HSV, VZV, measles virus, respiratory syncytial virus, influenza A and B viruses, parainfluenza viruses, and adenoviruses; bacterial pneumonia caused by a variety of gram-positive and gram-negative organisms; infection with protozoa, such as *P. jiroveci* and *Toxoplasma gondii*; infection with *Chlamydia* and *Mycoplasma*; and fungal pneumonia, caused especially by *Candida* and *Aspergillus*. Noninfectious causes of pneumonitis, such as pulmonary hemorrhage, aspiration pneumonia, rejection, and pulmonary damage from chemotherapeutic agents, also should be considered.

Retinitis and Other Eye Abnormalities

Chorioretinitis as well as optic atrophy, cortical visual impairment (also called cortical blindness), and strabismus occur in 17% to 41% of neonates with symptomatic congenital CMV infection and rarely in children born with asymptomatic congenital CMV infection.^{68,114,253,296,437} Although most retinal lesions in congenitally infected infants appear to be inactive at birth, some observations suggest that progression of preexisting lesions and late-onset new lesions resulting in vision loss may occur rarely in both symptomatic and asymptomatic congenitally infected infants.^{68,119} Retinitis does not seem to be a prominent part of perinatally or early postnatally acquired infection in immunologically normal infants but has been rarely reported to occur.^{283,382} Infants with primary immune disorders involving T-cell or NK-cell dysfunction, on the other hand, often have CMV viremia, usually at persistently high

titers, and CMV retinitis, which may be severe and necrotizing.³⁶³ CMV retinitis historically was a rare manifestation of CMV disease in solid-organ transplant recipients undergoing chronic immunosuppression for more than a year and in patients receiving chemotherapy for malignant disease.¹⁷³ In the 1980s, CMV retinitis emerged as a frequent manifestation of CMV disease in patients with severe immunosuppression, especially bone marrow transplant recipients and patients with AIDS. It probably is a result of hematogenous spread of the virus to the retina, with continued local viral replication. Despite the common occurrence of CMV retinitis in adults with AIDS, however, it is not often reported in children with AIDS.³⁰⁶

CMV produces characteristic white, perivascular infiltrates and hemorrhage, with a necrotic, rapidly progressive retinitis. It descriptively has been called “cottage cheese” retinitis and “ketchup” or “brushfire” retinitis.⁶⁴ Early, peripheral retinitis can be asymptomatic, or the complaints may be minimal and nonspecific; it is especially difficult to ascertain in infants and young children. It does not cause eye pain, photophobia, or conjunctivitis. When the retinitis has progressed, it can cause blurred vision, decreased visual acuity, visual field defects, and blindness. Young children and infants who have suffered visual loss as a result of CMV retinitis may exhibit strabismus or failure to fix and follow objects within their visual field. CMV retinitis also can progress rapidly to total blindness if the macula is involved. Immunosuppressed children from any cause who have CMV disease or persistently high levels of CMV DNA in their blood or plasma should receive regular expert ophthalmologic examinations to monitor for the development of sight-threatening retinitis. Establishing the diagnosis early may allow prompt institution of antiviral therapy, which may be sight saving.³⁰⁶

The ophthalmoscopic appearance of CMV retinitis usually is characteristic. However, in patients in whom the appearance of the retina is not typical or in whom the retinitis has progressed despite specific antiviral treatment, other causes of retinal lesions that should be considered include cotton-wool spots associated with hypertension, diabetes, connective tissue disease, anemia and leukemia, ocular toxoplasmosis, and candidal infection of the retina as well as syphilis, HSV infection, lymphocytic choriomeningitis virus infection, and VZV infection. Detection of the virus by culture or its DNA by a PCR-based method in vitreous fluid may help establish the diagnosis in difficult or atypical patients.¹⁶⁹ CMV antibodies also have been detected in the tears of patients with active ocular infections, including retinitis.⁴³⁶

CMV also has been associated in some studies with other unusual eye abnormalities. In coincidentally congenitally infected infants, microphthalmos, anophthalmia, optic nerve hypoplasia and coloboma, optic nerve atrophy, Peter anomaly, and irregular retinal pigment have been observed.¹⁸⁹ However, the role that CMV is playing in these anomalies is unclear and unsubstantiated by prospective studies.¹¹⁴ CMV does not appear to cause congenital cataracts.⁴⁵⁷ CMV also has been isolated from tears and has been associated with conjunctivitis in patients with CMV mononucleosis and AIDS as well as with corneal epithelial keratitis and disk neovascularization.³⁰⁰

Hepatitis

CMV hepatitis usually is manifested as mild to moderate hepatomegaly and mildly to moderately elevated serum hepatic enzyme levels in neonates with congenital CMV disease; in children who are bone marrow, heart, and lung transplant recipients; in patients with cancer or AIDS; in infants with primary immune deficiency of T-cell or NK-cell function; in patients with autoimmune disorders; and even in healthy infants and children experiencing a primary CMV infection.⁴⁹⁸ Infants with primary immune disorders of T-cell and NK-cell function may have progressive hepatomegaly, increasing aminotransferase levels, and the presence of CMV evident on histopathology in the liver. CMV hepatitis commonly occurs in conjunction with fever, thrombocytopenia, and lymphopenia or lymphocytosis. Jaundice and hyperbilirubinemia may occur, severe hepatitis or cirrhosis is exceedingly rare, and hepatic necrosis and liver failure caused by CMV hepatitis have not been documented convincingly in these patients. CMV infection also has been associated with granulomatous hepatitis.^{67,415} In addition, CMV hepatitis is a unique and prominent problem in children who have undergone liver transplantation.^{77,511} Most CMV hepatitis occurs 1 to 2 months after the patient

has undergone transplantation, but it may be noted as early as 2 weeks or as long as 4 months afterward.⁷⁹ It is more common and more severe after a primary CMV infection and is associated with liver transplantation from a CMV-seropositive donor and the use of OKT3 antibodies for severe rejection.⁴⁵⁹ CMV hepatitis in liver transplant recipients is characterized by prolonged fever, leukopenia, thrombocytopenia, elevated levels of liver enzymes, hyperbilirubinemia, and liver failure. Distinguishing between CMV hepatitis and acute rejection often is difficult, even with a liver biopsy, and the two commonly coexist. CMV infection also has been associated with ascending cholangitis, chronic rejection, and the vanishing bile duct syndrome in liver transplant recipients.^{79,357}

Infants with congenital CMV disease also may have hepatitis. The liver usually is smooth and nontender and commonly extends 3 to 5 cm below the right costal margin. Ascites may be present prenatally and may persist postnatally for 1 to 2 weeks. The hepatomegaly usually resolves by the time the infant is 3 months of age, and persistence beyond 1 year is highly unusual. Mild hepatitis generally is present, and aminotransferase levels in neonatal hepatitis caused by CMV rarely exceed 500 IU. Hyperbilirubinemia is present at birth in approximately one-third of neonates with congenital CMV and may be striking, with conjugated (direct) bilirubin levels up to 30 mg/dL.²⁴³ The abnormal results of liver function tests gradually resolve during the course of the first few weeks of life, and chronic hepatitis as a result of congenital infection with CMV is an unusual occurrence. Congenital CMV disease also has been associated with intrahepatic and extrahepatic biliary atresia in some studies, but the direct role of CMV in neonatal cholestatic disease is unclear.^{20,176,250} A neonate or infant with congenital CMV disease and recurrent, persistent or progressive hepatomegaly and hepatitis, despite antiviral treatment, may have an underlying primary immune deficiency of NK-cell or T-cell function.

The differential diagnosis of CMV hepatitis includes other causes of viral hepatitis, such as hepatitis A virus, hepatitis B virus, hepatitis C virus, Epstein-Barr virus, HSV, enterovirus, and adenovirus, as well as toxoplasmosis; other infections, such as bacterial ascending cholangitis; and noninfectious causes, such as ischemic injury, vascular thrombosis, hemolysis, rejection, and hepatitis induced by drugs or toxins. In neonates with a significant and persistent direct hyperbilirubinemia, the diagnosis of neonatal giant cell hepatitis or biliary atresia should be considered as well.

Gastrointestinal Disease

Serious gastrointestinal disease causing esophagitis, gastritis, gastric ulcers, gastric outlet obstruction, gastroenteritis, pyloric and small bowel obstruction, duodenitis, colitis, proctitis, pancreatitis, hemorrhage, and acalculous cholecystitis has been associated with CMV infection in immunocompromised persons, especially patients with AIDS or neoplastic disorders, patients with refractory autoimmune disorders receiving steroids and immunomodulators, and those who have undergone bone marrow, kidney, intestinal, or liver transplantation.^{145,319,332,361,397,512} Rarely, self-limited CMV gastroenteritis, colitis, and proctitis have been associated with CMV mononucleosis syndrome in apparently normal individuals.^{18,115,145,237,332,400,401} CMV enterocolitis has also been reported as a cause of intractable diarrhea, which often is bloody, in infants with congenital and postnatal CMV disease.^{144,145,186,242,319,397,399,427} Characteristic signs and symptoms in infants and children include nausea, vomiting, dysphagia, epigastric pain and tenderness, delayed gastric emptying, watery guaiac-positive stools or gastrointestinal hemorrhage, and disaccharide and monosaccharide intolerance.^{319,332,512} Severe disease may cause dehydration and failure to thrive. Endoscopy with biopsy is required to establish a definitive diagnosis and usually shows linear, localized, or punctate ulcers. Hemorrhagic lesions or diffuse erosion can occur in severe disease. Characteristic cytomegalic inclusion cells can be seen in the gastrointestinal endothelium, epithelium, and glandular tissue; CMV may be cultured from stool or biopsy specimens; or CMV DNA may be detected by PCR-based methods.²⁰¹ In addition, these patients often are viremic with CMV DNA by PCR detectable in their blood or plasma and occasionally have evidence of disseminated CMV infection with involvement of the lungs and retina. Infants with severe end-organ disease caused by CMV should receive an immunologic workup to exclude primary immune deficiency of T-cell or NK-cell function.

The differential diagnosis of CMV colitis includes infection with other viruses, especially HSV and adenovirus, and infection with bacteria, particularly *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia*, as well as *Clostridium difficile* and *Mycobacterium avium-intracellulare*. Parasitic infection with *Cryptosporidium*, *Giardia*, and amebae also should be excluded. The differential diagnosis of CMV esophagitis and gastritis includes HSV infection, *Candida* esophagitis, reflux esophagitis, and peptic ulcer disease.

Meningoencephalitis and Other Neurologic Disorders

CNS involvement is well described and occurs relatively frequently in infants with symptomatic congenital CMV infection. Although the severity of damage to the CNS during congenital infection varies greatly, postmortem examination of severely affected infants has demonstrated necrotizing encephalitis, especially in the deep periventricular structures, and scattered areas of necrosis and inclusion-bearing cells. Although direct viral infection of neural structures probably plays a major role in CNS disease in congenital CMV infection, infectious ventriculitis and vasculitis also may occur. FBDS also can be associated with severe forms of congenital CMV infection. In addition, because congenital CMV disease can be associated with marked thrombocytopenia, intracranial hemorrhage can contribute to CMV-related CNS injury.^{41,86,226,516} Clinical manifestations of this disease process include microcephaly, cerebral palsy, intracerebral calcifications, seizures, hemiparesis, developmental delay, ventriculomegaly, paraventricular cysts, intraventricular strands, periventricular leukomalacia, lissencephaly-pachygyria, porencephaly, schizencephaly, cortical malformations such as polymicrogyria, multifocal deep white-matter lesions and gliosis, atrophy from cerebral volume loss, parenchymal and ependymal cysts, periventricular cysts, cerebellar lesions, meningoencephalitis, and sensorineural deafness (Figs. 159.2, 159.3, and 159.5).^{105,285,354,491,508} Remarkably, despite the well-documented neuropathologic process in congenital disease, isolation of CMV from the cerebrospinal fluid (CSF) of a congenitally infected child is an extremely unusual finding.²⁴⁸ CMV DNA has been detected in the CSF of congenitally infected infants, and its presence at birth appears to identify infants at risk for a poor neurodevelopmental outcome.³¹

The differential diagnosis of symptomatic congenital CMV infection with neurologic disease includes congenital Zika virus syndrome, congenital toxoplasmosis, congenital HSV infection, congenital rubella syndrome, congenital infection with lymphocytic choriomeningitis virus, brain tumors such as craniopharyngioma, and calcified hematoma. In addition, congenital CMV disease involving the CNS also may be mimicked by genetic disorders such as tuberous sclerosis, Sturge-Weber syndrome, and Aicardi syndrome; metabolic conditions such as hyperthyroidism; α_1 -antitrypsin deficiency; galactosemia; peroxisome disorders such as Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease; urea cycle deficiencies; organic acidemias; and liposomal storage disorders.⁴⁰ Maternal exposure to drugs and toxins, especially isotretinoin, cocaine, and alcohol, also is included in the differential diagnosis. The presence or absence of intracerebral calcification and the pattern of calcifications when they are present may be helpful in distinguishing among these disorders. In addition, the appropriate microbiologic studies, chromosome analysis, metabolic studies, and drug screens should be performed.

In postnatal life, CMV meningoencephalitis appears to be rare yet well documented.³⁹ It may occur as a complication of CMV mononucleosis, as an isolated manifestation of primary CMV infection in a normal host, or as a primary or recurrent infection in an immunocompromised patient.⁴⁰¹ In infants, it may be the presenting condition of a primary immune deficiency of T-cell or NK-cell function, or SCID. Symptoms include headache, photophobia, nuchal rigidity, memory deficits, and inability to concentrate. CSF findings include mild mononuclear pleocytosis and slightly elevated protein. Although the virus is isolated from the CSF and brain parenchyma exceedingly rarely, neuropathologic findings of intranuclear inclusions and microglial nodules are characteristic.

CMV encephalitis may complicate adult and pediatric immunocompromised transplant recipients and patients with AIDS.⁴⁶ As many as 50% of patients with AIDS may have evidence of CMV infection of

FIG. 159.5 (A) Computed tomography scan and (B) ultrasound examination of the head of an infant with congenital cytomegalovirus disease. Both tests showed moderate asymmetric enlargement of the lateral ventricles with punctate periventricular calcifications.

the CNS at postmortem examination.³⁴⁴ CMV has been reported to cause a subacute, occasionally progressive encephalitis in patients with AIDS and has been implicated as a cofactor in the pathogenesis of the AIDS dementia complex seen in both adults and children.^{126,231,333,462,536} In this disease, CMV may be isolated from CSF, or CMV DNA may be detected in the fluid or brain by PCR-based methods.²⁰⁴ In children, this syndrome is characterized by weakness, confusion, and loss of developmental milestones.

The differential diagnosis of CMV encephalitis and meningoencephalitis in a normal host includes primarily infection with other neurotropic viruses, such as HSV, Epstein-Barr virus, VZV, enterovirus, and arboviruses. Neurosyphilis and tuberculous meningitis also should be considered. In immunocompromised patients, especially those with AIDS, the following should be added to the differential diagnosis of CNS infection: progressive multifocal leukoencephalopathy caused by papovavirus; HIV encephalitis; fungal CNS infection caused by *Cryptococcus neoformans*, *Candida* spp., *Aspergillus*, or *Histoplasma*; protozoal infections with *T. gondii* and, rarely, *P. jiroveci* and *Strongyloides stercoralis*; bacterial infections with *M. avium-intracellulare* and *Nocardia asteroides*; noninfectious diseases such as primary cerebral lymphoma and lymphomatoid granulomatosis; and vascular complications such as hemorrhage and infarction.²⁴ In immunosuppressed patients, more than one of these conditions can coexist in the CNS.

CMV also can invade the peripheral nervous system and cause a painful peripheral neuropathy in patients with AIDS.^{191,426,515} Ascending paralysis caused by myelitis, with or without vasculitis or necrosis, also can occur and may appear similar to Guillain-Barré syndrome.⁵¹⁵ In addition, CMV polyradiculopathy has been described in adult patients with AIDS and may occur in older children. This disease usually begins as leg pain and sacral paresthesias and may progress to weakness and flaccid paralysis. The CSF characteristically has a polymorphonuclear pleocytosis and moderately elevated protein level.²⁷⁰ The association of CMV infection with infantile spasms, Guillain-Barré syndrome, Charcot-Marie-Tooth disease, Huntington disease, Alzheimer disease, myasthenia gravis, and neuropsychiatric diseases (e.g., schizophrenia) has been reported, but a definite causal relationship between CMV and these diseases remains to be proved.^{39,275}

Deafness and Other Ear Disorders

Hearing loss is present at birth in 25% to 50% of infants with symptomatic congenital CMV infection and in approximately 10% to 15% of newborn infants with asymptomatic congenital CMV infection.²⁴³ By 18 years of age, up to 20% of children born with asymptomatic congenital CMV infection may develop progressive, sensorineural hearing loss, with 2% of them progressing to bilateral severe hearing loss requiring cochlear implants.^{292,296} The sensorineural hearing loss associated with symptomatic congenital CMV disease is often bilateral at birth or during early infancy, whereas hearing loss associated with asymptomatic congenital CMV

infection often begins unilaterally but may progress to bilateral hearing loss. In fact, 2% of children born with asymptomatic congenital CMV infection will develop bilateral sensorineural hearing loss by 18 years of age that is severe enough to warrant cochlear implantation.⁵²⁷ Given that congenital CMV infection affects 30,000 to 40,000 infants annually in the United States, this congenital infection probably is the most common cause of nonhereditary sensorineural deafness. Investigators have estimated that congenital CMV infection may account for as many as 40% of cases of congenital hearing loss.^{48,146,214} Progression or fluctuation of the hearing loss occurs in at least two-thirds of these children through the preschool years, and continued progression occurs through the school-aged and adolescent years.^{182,538} Although CMV has been detected in the endolabyrinth of infants who died from congenital CMV disease, whether this progressive deafness is caused by continued viral replication in the inner ear, reinfection with a new strain of virus, or a complex cascade of immunopathologic events remains unclear.¹²⁹ Mondini dysplasia of the temporal bones has been seen in infants with congenital CMV infection, but the importance of this observation relative to the pathogenesis of the progressive hearing loss commonly seen in congenitally infected infants is unknown at this time.⁵⁵ Some studies suggest that higher levels of CMV in urine and blood are present in neonates who develop hearing loss from congenital CMV infection,^{27,289,425,522} whereas other studies speculate that genetic mutations or inflammatory genes may play a role in CMV-associated hearing loss.^{353,356,433,450}

CMV has been isolated from the middle ear effusions of healthy and immunocompromised children with otitis media.^{108,161} In addition, CMV infection, defined serologically, has been associated with sudden-onset deafness, acute labyrinthitis, and Meniere disease.^{486,540,541} Older children who were born with asymptomatic congenital CMV infection also may exhibit differences in higher auditory function, even though they do not have sensorineural or conductive hearing loss.¹¹⁸

Myocarditis and Other Cardiovascular Disorders

Myocarditis has been described as a rare complication of severe in utero fetal and newborn congenital CMV disease and CMV mononucleosis in presumably otherwise healthy adults and children.^{367,500,526,541} CMV myocarditis and myopericarditis, occasionally accompanied by CMV hepatitis, has been reported in immunocompetent patients as well as immunocompromised patients.^{170,364} CMV myocarditis also has been seen in renal and heart transplant recipients, usually as part of a disseminated CMV infection and associated with graft rejection treated with high-dose immunosuppressive therapy.^{200,395,453} Myocarditis caused by CMV may be present in infants with primary immune deficiency disorders of T-cell and NK-cell function and SCID. Patients can have heart failure, cardiomegaly, electrocardiographic abnormalities, and poor left ventricular function on echocardiography; cytomegalic inclusion cells and the presence of CMV DNA can be documented by myocardial biopsy.

The association of CMV infection with other cardiac disorders such as congenital heart block, structural cardiac anomalies, and pericarditis is anecdotal, and a cause-and-effect relationship is not well documented.²⁶²

Thrombotic phenomena, often serious and life-threatening, have been associated with primary and active CMV infection in neonates, infants, adolescents, and adults, as well as transplant recipients and patients with HIV/AIDS.^{3,131,309} The virus may cause damage to endothelial cells, activate coagulation factors, and induce production of antiphospholipid antibodies.⁴⁷¹

CMV coronary endotheliitis with superimposed thrombosis and myocardial infarction has been described in adult heart transplant recipients and was reported in an infant who died of disseminated CMV disease with an apical ventricular aneurysm.^{331,440} CMV primary or acute infection also has been associated with venous and arterial thrombosis in previously healthy individuals, in patients undergoing solid-organ transplantation (especially renal and heart transplant recipients), and in infants with congenital and early postnatal CMV infection.^{2,32,309} Primary CMV infection has been associated with pulmonary embolism and portal vein thrombosis in an adolescent with CMV mononucleosis.^{2,3,14,288} CMV infection has been postulated to play a role in the pathogenesis of atherosclerosis and coronary artery disease in animal models, as well as in both normal persons and heart transplant recipients.^{206,251,320,324,496} High levels of CMV antibody have also been epidemiologically associated with coronary artery disease in studies in performed in many countries and continents, including India, Finland, the United States, and China.^{2,3,14,251,337,338,471}

CMV also has been associated with hypertension in animal (murine) models, but studies definitely linking CMV to hypertension in humans have not been definitive.¹⁰⁷

Endocrine System

Histopathologic evidence of involvement of the organs of the endocrine system is described well in both congenital and postnatally acquired disseminated CMV infections.²³⁰ Endocrine disorders such as Graves disease and diabetes insipidus have been associated with congenital CMV infection, but these reports may represent coincidental findings.^{325,439} Longitudinal studies are required to determine whether the autoimmune endocrinopathies in children with congenital rubella parallel the findings in children with congenital CMV infection. CMV infection also has been associated with autoimmune type 1 diabetes, although a specific cause-and-effect relationship has not been established.³⁶⁶ In addition, immunosuppressed patients, especially persons with AIDS, may manifest clinical endocrinopathies caused by CMV infection, such as adrenal insufficiency and adrenal necrosis.²⁰⁷ CMV inclusions also have been found in the pituitary gland of patients with AIDS, all of whom showed evidence of CMV encephalitis or disseminated infection elsewhere in the body.¹⁷¹ Moreover, involvement of the thyroid and parathyroid glands with CMV has been reported in adults with AIDS.¹⁸⁸

Genitourinary System

Disease of the male and female genitourinary system as a result of CMV has been reported. Patients with AIDS may have symptomatic epididymitis and cystitis caused by CMV.^{57,403,488} Lower urinary tract infections and hemorrhagic cystitis caused by CMV have been diagnosed in patients after they have undergone stem cell and solid-organ transplantation.³⁶⁵ CMV also commonly yet asymptotically infects the cervicovaginal secretions and semen of both healthy and immunosuppressed adults.^{256,290}

Skin

Cutaneous manifestations of CMV infection are described well and can occur with both congenital and acquired CMV infection.³⁰³ Infants with symptomatic congenital infection may have nonpalpable petechiae, purpura, or bruises, usually as a result of thrombocytopenia. Violaceous or dark magenta infiltrative papules or nodules, called “blueberry muffin” lesions, also may occur, but these lesions are more characteristic of congenital rubella syndrome. The skin lesions associated with acquired CMV infection usually are localized cutaneous ulcers or a widespread, exanthematous, maculopapular eruption, although vesiculobullous lesions also have been described.³⁷⁸ CMV mononucleosis syndrome in

adults and children may be accompanied by a maculopapular, rubelliform rash that may be pruritic. In addition, ampicillin-associated rashes may occur with CMV mononucleosis. CMV also may cause a cutaneous, leukoblastic vasculitis.⁴⁴¹ Well-demarcated, ulcerated lesions that show histopathologic evidence of CMV infection may be seen in immunocompromised patients who have undergone transplantation or in those who suffer from AIDS. Finally, CMV may play a cofactor role with human herpesvirus type 8 in the neoplastic process in Kaposi sarcoma, but definitive proof of a causal relationship remains to be shown.

Unusual Associations

CMV infection, either congenital or acquired, has been detected in association with a wide variety of conditions, including defects in tooth structure and the formation of enamel, arterial or venous thrombosis, atherosclerosis, portal vein thrombosis associated with protein S and protein C deficiency, unexplained fevers in burn patients, bacterial sepsis in burn patients, congenital eventration of the diaphragm, inguinal hernia, and fatal *Staphylococcus epidermidis* infection in very low-birth-weight infants.* CMV infection also may be involved in the genesis and maintenance of immunopathologic phenomena, such as allograft rejection in solid-organ transplant recipients and graft-versus-host disease in bone marrow and stem cell transplant recipients, as well as autoimmune diseases.^{284,508} Case reports have linked primary CMV infection with the onset of autoimmune disorders or recurrent CMV infection with worsening of autoimmune disease.^{219,381,509} CMV also has been associated with hemophagocytic syndrome in adults and children.²⁸⁴ However, given the common occurrence of CMV infection, it is difficult to determine whether the relationships are coincidental or comorbid, rather than part of a cause-and-effect relationship.

LABORATORY DIAGNOSIS

Detection of the Infectious Agent

CMV can be isolated in cell culture with fibroblast cell lines such as human foreskin fibroblasts and human embryonic lung fibroblasts.⁴⁴⁸ Specimens that contain a high titer of virus, such as those from congenitally infected infants, may show growth in 24 hours. Some specimens, such as those from persons with acquired asymptomatic infection, may require as long as 6 weeks for detectable growth, but most cultures grow in 1 to 2 weeks. CMV has been isolated from a variety of specimens, including urine, saliva, nasopharyngeal and sinus washings, conjunctiva, tears, middle ear fluid, breast milk, semen, cervicovaginal secretions, stool, CSF, peripheral white blood cells and plasma, amniotic fluid, bronchial lavage samples, and biopsy or autopsy specimens. One study also evaluated umbilical cord samples as a method of diagnosis and applied it to newborn screening for congenital CMV.⁵⁰⁴ Urine may be collected in a pediatric urine bag or trapped by cotton balls inserted in the diaper.⁴²⁹ Saliva samples should be collected from the infant's mouth with a swab, allowing the infant to suck on the swab for a short period of time to make sure the swab is saturated with saliva before being placed in viral transport media. Waiting at least 1 hour after breast-feeding is also recommended for saliva swab collection because small amounts of CMV may be present in breast milk and produce a false-positive result in some breast-fed infants.⁷² All samples for isolation of viruses (except blood, which should be at room temperature) should be held at 4°C (on wet ice or in a refrigerator) until processed in the virology laboratory. Specimens for isolation of virus should be inoculated within hours of collection for an optimal isolation rate. Although isolation of CMV proves that a productive infection is present, it does not confirm an etiologic relationship with the disease process and requires careful interpretation within the patient's clinical context. The exception is detection of CMV by culture, shell vial assay or CR methods in a sample or urine, saliva, or blood/plasma obtained in the first 21 days of life of a newborn because this will establish that a congenital CMV infection is present. Clinical correlation will then be needed to establish any organ involvement associated with the congenital infection (Box 159.5).

An adaptation of tissue culture is a low-speed centrifugation enhancement, monoclonal antibody culture technique, also called a *shell vial*

*References 2, 14, 28, 32, 56, 218, 260, 281, 288, 308, 311, 479, 496.

BOX 159.5 Virologic Testing to Establish the Diagnosis of Congenital Cytomegalovirus (CMV) Infection

Detection of CMV by culture or polymerase chain reaction in saliva or urine or blood in first 21 days of life
 CMV immunoglobulin M antibody (should be confirmed with CMV testing of urine or saliva) at birth
 Detection of CMV DNA in newborn screening dried blood spot
 Detection of cytomegalic inclusion cells or detection of CMV by immunohistochemical staining in tissue from clinically involved organs from biopsy or autopsy specimens

assay. In this test, inoculated tissue culture cells in small vials are stained with a fluorescein-conjugated monoclonal antibody to either an early or a late CMV antigen (or both). Cells infected with CMV exhibit nuclear and membrane fluorescence 18 to 72 hours after inoculation. This rapid viral diagnostic technique is especially reliable with saliva, urine, and BAL specimens and has been applied with variable results to blood and tissue specimens.^{198,385} However, maximal sensitivity and specificity are obtained when shell vials are used as an adjunct to and not in place of routine tissue culture. CMV-infected cells also can be detected by direct immunofluorescence assay on exfoliated cells in BAL specimens or in frozen tissue specimens.²²⁰ These procedures, however, require a laboratory experienced in direct immunofluorescence assay technique.

Real-time PCR-based methods, both quantitative and qualitative, coupled with automated nucleic acid extraction systems, are available in many clinical and reference laboratories for detection and quantitation of CMV DNA in a variety of clinical samples (saliva, urine, blood, amniotic fluid, vitreous samples, and tissue).⁶² These very sensitive tests may be used to detect and to quantify CMV DNA in a variety of samples and are useful for diagnosis or prediction of CMV disease, as well as for monitoring response to antiviral treatment.^{82,98,128,134,197,462,468,475} Recently, PCR assays for detection of CMV DNA in saliva specimens, urine specimens (liquid urine collected by bags or using cotton balls in diapers), and dried blood spot (DBS) specimens from newborn screening Guthrie cards have been applied as tools to screen newborns for congenital CMV infection^{96,432,429,552} (see Box 159.5). Detection of CMV DNA in the CSF of immunocompromised patients with AIDS, of patients with primary immune disorders, and of transplant recipients seems to be a reliable diagnostic method for detection of CMV infection of the CNS, and detection of CMV DNA in the CSF of neonates with congenital CMV disease correlates with poor neurodevelopmental outcome.^{31,113,204,546} Similarly, detection of CMV DNA by PCR analysis in vitreous fluid provides persuasive evidence that a patient's retinitis is CMV related.¹⁵⁴ CMV DNA also may be detected in the peripheral white blood cells and plasma of patients with CMV infection, and detection of CMV DNA in the plasma or serum of neonates and immunocompromised patients appears to correlate with severity of disease and viral dissemination.^{343,456,474,475} Detection of CMV DNA in amniotic fluid provides prenatal diagnosis of congenital CMV infection and, when correlated with fetal ultrasonography and other clinical evaluations of the fetus, supports the presence of CMV-associated in utero disease.³⁰⁷ PCR assays also have detected CMV DNA in DBS or Guthrie cards collected, as well as in urine and saliva, as part of neonatal screening programs and used to diagnose congenital CMV infection and disease.^{48,51,71,72,522}

Another use for PCR-based diagnosis of CMV infection is the very early diagnosis of CMV infection in high-risk patients, such as transplant recipients, before the development of potentially fatal CMV disease, such as pneumonitis. This approach may allow preemptive antiviral therapy to be initiated when CMV infection appears active but before overt disease is detected.^{81,547} CMV quantitative DNA detection by PCR assay is now standard for monitoring a patient's response to antiviral therapy and should be correlated with the resolution of CMV-related clinical symptoms.^{150,195}

CMV pp65 antigen also may be detected in the white blood cells of patients with CMV infection and disease, but this CMV antigenemia test is now rarely used by clinical laboratories as a rapid, same-day screen for CMV viremia. Even though it is relatively easy to perform and the degree of antigenemia may be quantitated to monitor response to antiviral therapy, it has been replaced by quantitative PCR assays in most clinical and reference laboratories.¹⁵⁰

Exfoliated cells in urine or BAL specimens or cells in tissue obtained by biopsy can be examined for histologic evidence of CMV infection. Cells that are infected productively with CMV are enlarged, have type A Cowdry intranuclear inclusions, and occasionally have perinuclear inclusions. The appearance of these cells is characteristic and has been likened to owl's eyes. Immunohistochemical staining with immunoperoxidase can be used to augment the detection of these typical cells. The presence of these cells correlates with the presence of active CMV disease and may be useful clinically. In addition, viral load assessed by quantitative PCR of BAL specimens helps with diagnosis of CMV pneumonitis in immunocompromised patients.²⁴⁰

Serology

Standard serologic techniques also can be applied to the diagnosis of CMV infections. CMV IgG antibody can be determined in serum by several different methods, including complement fixation, hemagglutination inhibition, indirect fluorescent antibody assay, anticomplement immunofluorescence assay, enzyme-linked immunosorbent assay (ELISA), and latex agglutination and neutralization tests. ELISA and the indirect fluorescent antibody assay are used most commonly in clinical virology laboratories. The presence of CMV IgG antibody in a single serum specimen implies that the patient at some time has been infected with CMV. On the other hand, a negative IgG antibody determination is good evidence against current or past CMV infection because CMV antibody usually is present at the time of infection and persists for life. Severely immunocompromised patients, especially bone marrow transplant recipients, or infants and children with a primary immune deficiency, however, can lose their ability to make IgG antibody and become CMV seronegative, even though they are infected actively with CMV. This occurrence has a poor prognosis and requires immediate reconstitution with antibody and aggressive antiviral therapy until immune reconstitution is achieved. Primary infection with CMV is documented best by clear seroconversion from negative to positive CMV IgG antibody. A fourfold rise in CMV IgG antibody titer is not diagnostic of a primary infection because reactivation or reinfection also can cause titers to fluctuate. In addition, the height of the titer or ELISA index in a single serum specimen is not diagnostic of a recent infection or indicative of severity of CMV disease.

CMV IgM antibody can be determined in serum by radioimmunoassay, indirect fluorescent antibody assay, or ELISA. Both the indirect fluorescent antibody assay and ELISA are used commonly in clinical laboratories, although some indirect fluorescent antibody assays have a considerable false-positive rate. Accurate interpretation of CMV IgM antibody results requires knowledge of the methods used and careful consideration of the clinical context to exclude diseases that produce cross-reacting antibody or polyclonal responses. Test methods also should remove rheumatoid factor from the test serum, a common cause of false-positive IgM reactions. If the test is performed properly, the presence of CMV IgM antibody implies a current or recent primary CMV infection. In healthy adults, CMV IgM antibody usually persists for 6 weeks and may be present for as long as 3 to 12 months, rarely even longer, after the primary infection.¹³⁶ Commercial immunoblot and avidity assays may be used to supplement conventional CMV IgG and IgM serology.²⁹⁷ The CMV IgG avidity index and IgM immunoblot assay are now available in clinical reference laboratories in many countries and continents, including Europe, Asia, and the United States. This testing may be used to help time a suspected primary infection with CMV (see Box 159.4).^{163,298,402,416} A low avidity index (30%) suggests a recent primary infection, usually within 3 months, because low to moderate CMV avidity anti-CMV antibody may persist for 18 to 20 weeks after primary CMV infection.²⁹⁸ A high avidity index (>60%) suggests a past or recurrent CMV infection.²⁰⁵ There are several manufacturers of these supplemental CMV assays, and results may vary among manufacturers,

so interpretation should be within clinical context and in concert with other CMV testing, if available.⁴⁰² In immunocompromised adults experiencing clinically significant reactivation infection with CMV, CMV IgM antibody may be detected for prolonged periods.³⁴⁵ The sensitivity and specificity of CMV IgM antibody determination in the diagnosis of acquired, primary CMV infection or clinically significant reactivation infection in infants and children have not been studied systematically, although clinicians frequently use this test for this purpose.

Western blot assays using viral structural proteins separated from purified viral particles or from recombinant viral proteins appear to be sensitive and specific for detection of glycoprotein-specific CMV IgG and IgM. Currently, these tests are available only in research or reference laboratories.²⁹⁹

Recently, two interferon- γ release assays (IGRAs) that measure cell-mediated immunity against CMV, the cytomegalovirus enzyme-linked immunosorbent spot (ELISOT) and CMV QuantiFERON assays, have been evaluated as potential biomarkers for primary versus nonprimary maternal CMV infections and as predictors of congenital CMV transmission. They also have been used to detect protective, CMV-specific T-cell responses in transplant recipients at risk for CMV infection and CMV disease. These assays are now available in some clinical and reference laboratories, and as more clinical experience evolves on their clinical utility, CMV IGRAs testing may become more common in certain at-risk groups of patients.^{1,180,438}

Laboratory Diagnosis of Specific Clinical Syndromes

Pregnancy

Diagnosis of primary maternal CMV infection is best made by de novo seroconversion of virus-specific CMV IgG antibody or by the presence of both CMV IgG antibody and CMV IgM antibody associated with a low IgG avidity index.⁵⁵⁹ For timing of the onset of CMV infection (before or in early pregnancy), CMV avidity testing is most helpful if performed during the first or early second trimester.¹⁶³ In primary maternal CMV infection, the risk for transmission of CMV to the fetus is approximately 40%, and it is up to 25% overall to the fetus for development of sequelae of some type. A maternal recurrent infection may result from reactivation of the woman's own endogenous strains of CMV or by reinfection with a new strain of CMV. Recurrent CMV infection is difficult to diagnosis prenatally and may be considered if there is a significant rise in CMV IgG antibody, with the presence of IgM and a high avidity IgG index. The diagnosis of recurrent CMV infection in the mother can also be considered if she is CMV IgG antibody positive and CMV IgM antibody negative at the beginning of pregnancy yet gives birth to a congenitally infected but usually symptom-free neonate. Routine serologic screening of pregnant women for CMV infection is controversial; although recommended by some experts, it is not currently performed in the United States or Canada.³⁰⁴ However, selective serologic screening for diagnosis should be performed for women who request it and for women in high-risk circumstances, including those with clinical evidence of CMV infection, such as mononucleosis during pregnancy or detection of fetal abnormalities on screening ultrasonography suggestive of in utero CMV disease.¹⁴⁷ Serologic screening and counseling may also be considered for child care workers and for women with a young child or toddler in the household. Prenatal diagnosis of in utero CMV infection of the fetus is best accomplished by amniocentesis, which should be done at least 7 weeks after the presumed time of maternal primary CMV infection and after 21 weeks' gestation.^{235,430} This interval is important because it may take 5 to 7 weeks (at least 2 weeks) after maternal infection to produce fetal infection and subsequent replication in the kidney for a detectable quantity of CMV to be detected in the amniotic fluid.²³⁵ Amniotic fluid may be sent for CMV culture or detection of CMV DNA by qualitative or quantitative PCR. Quantitative determination of CMV DNA in amniotic fluid that shows very high levels of DNA may predict more serious disease in the fetus and poorer outcome in the neonate. After diagnosis of maternal primary or recurrent CMV infection, monitoring of the fetus by serial ultrasound examinations should be performed every 2 to 4 weeks to detect abnormalities, which may aid in management.

Congenital Infection

Viral culture or CMV culture is the traditional diagnostic test for congenital infection with CMV, but it is being replaced by molecular methods in most clinical laboratories.¹³² The diagnosis of congenital CMV infection is established by isolation of the virus or detection by PCR of viral CMV DNA from urine or saliva obtained from the infant during the first 3 weeks of life⁴²⁹ (see Box 159.5). Cell culture of urine or saliva has been used successfully to screen large numbers of neonates for congenital CMV, as well as diagnose individual patients clinically.^{132,138,359,478,564} Urine cultures obtained after 3 weeks of life must be interpreted cautiously because perinatally acquired and transfusion-acquired infections with CMV may be manifested as early as 3 weeks of age.⁴⁴² Detection of nuclear inclusion-bearing renal epithelial cells in urinary sediment collected in the first 2 weeks of life also implies the presence of congenital infection. This technique is insensitive, however, compared with cell culture and is important only historically. Detection of CMV DNA in the urine, saliva, blood, or CSF of neonates by DNA PCR amplification techniques correlates with congenital infection and disease, and this method is currently used by most clinicians and laboratories for diagnosis of congenital CMV.^{31,80,134,343} Detection of CMV DNA in DBS or Guthrie cards collected for neonatal metabolic screening also has been used for the retrospective and prospective diagnosis of congenital CMV infection and disease.^{49,50,52,551} However, this method may not detect all congenitally infected neonates, especially those with silent or asymptomatic infection, because the level of CMV in blood is lower in asymptomatic congenital CMV infection. Studies evaluating real-time PCR assays performed on DNA extracted from DBS samples used to screen neonates for other congenital conditions have mostly shown DBS relatively insensitive for neonatal screening programs when compared with traditional methods but possibly are useful for identification of neonates with symptomatic disease or at high risk for sequelae.^{71,302,432,551} Genotyping may be performed by PCR assays on DNA extracted from DBS samples, providing a tool to study the possible association of CMV gB or gH genotype with disease in neonates.^{138,141} Real-time PCR assays performed on saliva specimens (both liquid and dried) have shown high sensitivity compared with traditional saliva rapid culture and may be a potential screening tool for diagnosis of congenital CMV in neonates.^{49,50,52,72,467,508,553,554} Currently, two approaches to newborn screening for congenital CMV infection have been proposed. One is targeted testing for congenital CMV infection of newborns who fail their newborn hearing screening, by CMV testing of urine or saliva by culture or PCR assays done in the first days of life, because CMV is a cause of congenital hearing loss.^{183,225,504} The other approach is universal newborn screening for congenital CMV, testing all newborns for CMV at birth, by detection methods applied to urine, saliva, or DBS from newborn screening Guthrie cards.^{225,405} Some birthing centers have adopted targeted newborn testing for congenital CMV, and even two states have laws providing for targeted testing. However, neither approach at this time is adopted by all birthing centers or all states in the United States or all countries in the world, but discussions among CMV experts around the world continues concerning the relative merits of targeted versus universal newborn screening for congenital CMV infection.⁴⁰⁵

Newborns with virologic evidence of congenital CMV infection should receive a thorough clinical, laboratory, and imaging evaluation to determine whether there is end-organ involvement (Box 159.6). Also, neonates with high CMV DNA levels by quantitative PCR methods appear to be at highest risk for severe illness in the neonatal period and for sequelae such as progressive or late-onset hearing loss and therefore are potential candidates for CMV antiviral therapy, especially if ongoing clinical trials show benefit.^{289,522}

An in utero CMV infection may be suspected if routine fetal anatomy scans performed at 19 to 20 weeks' gestation show intrauterine growth restriction, microcephaly, echogenic bowel, fetal ascites, hepatosplenomegaly, or malformations of the brain. Fetal condition also can be determined by serial fetal ultrasound examinations or fetal MRI in special circumstances.^{113,182,313} Most in utero fetal CMV infections, however, are asymptomatic.⁶⁵ The diagnosis of fetal intrauterine CMV disease in single, twin, and multiple births may be established by isolating the virus from amniotic fluid or detecting CMV DNA by

BOX 159.6 Initial Evaluation of Newborn Confirmed to Have Congenital Cytomegalovirus (CMV) Infection (Asymptomatic or Symptomatic at Birth)

Physical, neurologic, and neurodevelopmental examination

Weight, length, and head circumference measurements

Laboratory testing

- CBC, differential platelet count
- Liver function tests (AST, ALT, total and direct bilirubin, GGT)
- Kidney function tests (BUN and creatinine)
- Coagulation studies (select patients)
- Whole blood or plasma for CMV DNA quantitative PCR to establish presence and level of viremia as risk factor for later sequelae
- TRECs newborn screen for severe combined immunodeficiency syndrome (check results if done)

Hearing evaluation by auditory brainstem response

Ophthalmology evaluation

Neuroimaging (one or more of the following, depending on clinical presentation)

- Neonatal head ultrasound
- CT scan, unenhanced
- MRI, unenhanced

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood count; CMV, cytomegalovirus; CT, computed tomography; GGT, γ -glutamyl transferase; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; TRECs, T-cell receptor rearrangement excision circle.

PCR amplification in amniotic fluid obtained at least 2 weeks after the suspected time of maternal primary infection and after 21 weeks' gestation.^{226,430,560}

Fetal blood samples that show the presence of CMV DNA by PCR assay, CMV IgM antibody, thrombocytopenia, leukopenia, or elevated liver function test results also provide supportive evidence of CMV-associated fetal disease and may predict severe disease.

Prenatal screening of pregnant women and prenatal diagnosis of congenital CMV infection should be accompanied by consultation with a maternal-fetal medicine specialist as well as a pediatric infectious diseases specialist and a prenatal counselor knowledgeable about all the possible outcomes that can occur and all the options that are available to the parents and physician.^{162,346,416}

Standard serologic tests also can be applied to diagnose congenital infection with CMV, but this approach is cumbersome, retrospective, and rarely used clinically. The absence of CMV IgG antibody in cord blood may rule out congenital infection, unless the infant has a primary immune disorder affecting antibody response to CMV, whereas its presence may imply passive transfer from the mother or indicate a congenital infection. Serial serologic specimens also can be obtained when the infant is 1, 3, and 6 months of age. If CMV IgG antibody levels disappear during the infant's first months of life, congenital infection is ruled out. However, if CMV IgG antibody persists, the infant either was infected congenitally or acquired CMV infection perinatally or postnatally. The presence of CMV IgM antibody in cord or infant blood collected in the first 3 weeks of the infant's life suggests the diagnosis of congenital CMV infection.^{212,480} However, CMV IgM antibody is insensitive (as low as 22%) compared with urine or saliva CMV culture or CMV DNA detection for the diagnosis of congenital infection.³⁴³ In one study, positive CMV IgM antibody was found in only 49% of newborns with symptomatic congenital CMV infection and 22% of newborns with asymptomatic congenital CMV infection.⁶⁰

Perinatal and Postnatal Infection

The diagnosis of perinatal infection with CMV is difficult to establish but is documented best by a negative CMV viral culture or negative CMV DNA PCR analysis of urine or saliva and negative CMV IgM antibody level at birth or in first 21 days of life, followed by a positive viral culture and positive CMV IgM antibody at 8 to 16 weeks of age and persistence of CMV IgG antibody beyond 4 to 6 months of age.

Postnatal primary CMV infection is diagnosed by CMV IgG seroconversion, the presence of CMV IgM antibody, and CMV excretion or "shedding" detected by culture or PCR in saliva, urine, and other body fluids.

Cytomegalovirus Syndromes in Immunocompromised Hosts

In immunocompromised patients, determination of whether serologic or virologic evidence of active CMV infection correlates with disease is difficult because CMV commonly is shed from saliva, urine, and respiratory tract secretions in these patients without clear evidence of a disease process.²²² Therefore detection of a productive virus infection in the organ system suspected to be involved is often necessary to establish the diagnosis of CMV disease in an immunocompromised patient. For example, interstitial pneumonitis caused by CMV is documented best by an open-lung biopsy specimen that shows characteristic CMV histopathologic features and positive viral culture.¹²² Detection of CMV in BAL specimens also correlates with lung biopsy results for diagnosis of CMV pneumonitis.^{122,197} In addition, CMV viral load in BAL specimens greater than the plasma viral load, associated with signs and symptoms associated with pneumonitis, suggests CMV as the cause of pneumonia in transplant recipients. Similarly, the diagnosis of CMV hepatitis or colitis is documented best by the presence of cytomegalic inclusion cells, isolation of CMV, or detection of CMV by DNA PCR or immunohistochemical stains from biopsy specimens. If biopsy of the suspected organ is not feasible or practical, then detection of CMV viremia or rising titers of CMV DNA by quantitative PCR can support the diagnosis because it often precedes or accompanies serious disease, such as CMV pneumonitis in bone marrow or solid-organ transplant recipients, CMV retinitis or colitis in patients with AIDS, or disseminated disease in infants with primary immune deficiency syndromes.^{195,475,514}

Prospective monitoring of high-risk patients by serial samples of blood or plasma for quantitative CMV DNA PCR analysis or, alternatively, by CMV cultures of urine or blood or bronchial lavage samples and collection of serum to detect seroconversion by serologic testing is indicated and often performed because positive tests indicate the need for preemptive therapy with a CMV-specific antiviral agent, such as ganciclovir or valganciclovir, when CMV infection is active but before overt disease develops.^{195,407,449,497}

TREATMENT

Antiviral agents with activity against CMV include derivatives of acyclovir, such as ganciclovir and valganciclovir, as well as foscarnet and cidofovir (Fig. 159.6).^{*} Investigational agents, such as maribavir, are in clinical trials to determine safety, antiviral effects, and efficacy for treatment and prevention of CMV infection in transplant recipients and possibly, in the near future, for congenital CMV disease.^{34,317,318,542,543} However, the lack of reliable CNS penetration of maribavir may limit its clinical utility in high-risk patients with CMV disease. Acyclovir and valacyclovir also may have limited activity against CMV under certain conditions. In addition, biologic agents such as immune globulin and CMV hyperimmune globulin may benefit selected patients, and novel approaches such as cell-based, cytotoxic T-cell adoptive immunotherapy also are being investigated in clinical trials.^{25,63,224,347,393,503} Treatment is beneficial for adult and pediatric immunocompromised hosts as well as for neonates with congenital CMV disease.[†] Normal hosts with severe CMV disease also may benefit from antiviral therapy.⁴⁰¹

Treatment of CMV-associated disease, such as retinitis, pneumonitis, hepatitis, colitis, esophagitis, or encephalitis, in immunocompromised hosts, such as those patients with primary immune deficiency disorders, AIDS, or transplant recipients, usually involves a 2- to 3-week period of induction therapy with an intravenous antiviral medication, usually ganciclovir, as first-line treatment.^{83,122,143,178,216,245,264,527} In special circumstances, such as suspected drug resistance or marrow suppression, foscarnet or cidofovir may be indicated.^{164,489} The administration of ganciclovir plus foscarnet or cidofovir is advocated by some experts

†References 83, 122, 143, 168, 178, 216, 228, 233, 264, 271, 272, 274–276, 305, 349, 410, 413.

FIG. 159.6 Structures of acyclovir, ganciclovir, and foscarnet.

for treatment of CMV disease in infants with primary immune deficiency of T-cell or NK-cell function, to avoid emergence of resistant strains, until immune reconstitution is achieved. The induction period should be accompanied by clinical improvement and a virologic response, with reduction in the blood quantitative CMV DNA PCR titers. If the host is expected to remain severely immunocompromised after receiving successful induction therapy, or is awaiting immune reconstitution, maintenance therapy at the same dosage as treatment levels or, alternatively, a reduced dosage schedule, three to five times a week, administered intravenously or orally is indicated through the expected period of immune suppression. In patients with AIDS, primary immune disorders of T-cell or NK-cell function, solid-organ transplant recipients receiving high levels of immunosuppression, and bone marrow/stem cell transplant recipients who have not yet engrafted and shown T-cell function may receive full doses of antiviral medication as maintenance therapy. Such therapy is usually continued indefinitely, or until immune reconstitution or resolution of immune suppression.¹⁵¹ In patients with AIDS or other immune deficiency conditions who have refractory CMV retinitis, treatment with a ganciclovir implant by an ophthalmologist may augment systemic therapy, but published experience evaluating this approach in infants and children is limited.^{94,505} Valganciclovir, an orally bioavailable prodrug of ganciclovir, appears to be as effective as is intravenous ganciclovir for induction therapy for CMV retinitis and for mild to moderate CMV disease in solid-organ transplant recipients.^{159,316} Clinical experience has shown valganciclovir is also useful for other CMV-associated illnesses in mild to moderately ill patients. If, despite administration of antiviral therapy, CMV disease persists or progresses or if a virologic response does not occur, drug resistance should be considered. Resistance to ganciclovir has been documented most commonly in patients with AIDS, but it also can occur in patients with primary immune deficiency disorders of T-cell and NK-cell function or malignant neoplasms and in solid-organ and stem cell transplant recipients.^{111,244} Most ganciclovir-resistant CMV strains have a mutation in the UL97 phosphotransferase gene, but specific mutations in the UL54 DNA polymerase gene also may occur alone or in combination with UL97 mutations.¹⁰⁰ Most ganciclovir-resistant CMV strains are susceptible to foscarnet but may exhibit cross-resistance to cidofovir, and strains simultaneously resistant to ganciclovir, cidofovir, and foscarnet also rarely may occur.^{112,489} Reports of repopulation of previously susceptible wild-type strain of CMV may occur after discontinuation of ganciclovir in patients in whom a ganciclovir strain has emerged.¹⁵² Resistant strains of CMV may compartmentalize in the eye or brain and cause progressive disease, even if plasma and peripheral sites appear to harbor susceptible strains.

The association of CMV immune globulin administration and acute and long-term clinical outcomes in transplantation has not been well defined.^{53,160,175} The administration of ganciclovir along with intravenous

immune globulin (IVIG) or CMV hyperimmune globulin to bone marrow transplant recipients with CMV pneumonitis has been shown to increase survival over that of historical controls who were treated with a variety of other antiviral regimens, including ganciclovir alone, immune globulin alone, acyclovir, vidarabine, and interferon.¹⁶⁰ However, differences in the method used to diagnose CMV pneumonitis, duration of illness, and treatment regimens between study subjects and historical controls obscure interpretation of these studies.^{126,307} Nonetheless, CMV-associated interstitial pneumonitis in bone marrow transplant recipients, and other types of CMV disease in immunocompromised hosts, may be an immunopathologic process, and combination therapy may prevent active virus replication (ganciclovir, foscarnet, cidofovir) while enhancing immune responsiveness of cellular immunity in immune globulin-deficient patients or blunting the immune response to viral antigens already expressed on CMV-infected cells.^{246,454} CMV hyperimmune globulin administered to liver transplant recipients has been shown to increase the risk for organ rejection but results in greater long-term graft and patient survival.¹⁷⁵ In pediatric and adult heart transplant recipients, administration of CMV hyperimmune globulin with or without antiviral prophylaxis is also associated with decreased mortality and graft loss.^{463,464}

Oral maribavir has been reported in clinical trials to be possibly effective for CMV prophylaxis for prevention of CMV infection in stem cell transplant recipients and treatment of refractory or drug-resistant CMV in transplant recipients.^{503,544} Clinical trials for treatment of congenital CMV infection may also be conducted in the future. Standard IVIG or CMV hyperimmune globulin, although possibly beneficial in selected patients when combined with specific antiviral therapy, should not be used alone for the treatment of established CMV infections in immunocompromised patients.^{175,323,464} The combination of high-dose corticosteroids with ganciclovir does not appear to improve survival in bone marrow transplant recipients with biopsy-proven CMV pneumonitis.⁴¹¹ On the other hand, a regimen combining ganciclovir with hematopoietic growth factor may allow ganciclovir to be continued in selected patients with mild marrow toxicity.

CMV hyperimmune globulin or CMV-enriched immune globulin has been shown to be of possible benefit during pregnancy in women experiencing a primary CMV infection, by reducing fetal disease in the CMV-infected fetus and by reducing transmission from mother to fetus.⁴⁰⁶ Case series and nonrandomized studies show that CMV hyperimmune globulin appears to reduce the risk for transmission of CMV to the fetus from 40% to 16% when administered during a primary maternal infection during pregnancy, may reverse fetal abnormalities, and may improve outcome in the CMV-infected fetus with in utero disease.^{87,286,347,517} One recent randomized clinical trial showed that treatment with hyperimmune globulin reduced the transmission of CMV to the fetus in mothers experiencing a primary CMV infection

during pregnancy from 44% to 30%. However, this difference was not statistically significant.⁴¹⁸ Currently, another randomized, double-blind, placebo-controlled clinical trial evaluating CMV hyperimmune globulin for prevention of CMV transmission to the fetus during primary maternal CMV infection is underway in the United States (NCT01376778; www.clinicaltrials.gov).

Treatment of infants with symptomatic congenital CMV infection with the antiviral agent foscarnide was reported first by Feigin and colleagues in 1969 and 1971.¹⁶⁷ More recent reports suggest that antiviral agents, such as ganciclovir and valganciclovir, benefit congenitally infected infants.^{84,287,328,329,342,358,359,446,558} Anecdotal reports, case series, and randomized clinical trials have shown clinical and virologic improvement in congenitally infected neonates treated with ganciclovir and valganciclovir.^{232,348,359,414,495,506} A multicenter phase I and II study of the pharmacokinetics, antiviral effects, and safety of intravenous ganciclovir was conducted in 47 neonates with symptomatic congenital CMV disease and neurologic involvement.^{502,535,567} In this study, a 6-mg/kg dose of ganciclovir administered by a 1-hour infusion every 12 hours for a period of 6 weeks produced a significant reduction in the quantity of urinary virus excretion; however, viral shedding recurred when ganciclovir treatment was discontinued. Neutropenia, thrombocytopenia, and elevated levels of liver enzymes also were observed. Limited clinical follow-up in 30 of the original 47 infants showed that hearing loss improved or stabilized in 16% of the treated infants. Subsequently, a phase III, multicenter, randomized clinical trial enrolled 100 infants and was completed in 1999.²⁷⁴ In this study, ganciclovir treatment in the neonatal period appeared to have an impact on hearing loss by slightly improving hearing, maintaining normal hearing, or preventing hearing deterioration, as measured when the infants reached 6 and 12 months of age. Because only 44% of the enrolled infants were assessed in follow-up at 1 year of age, a long-term follow-up study of treated infants is needed to determine whether the early beneficial effects last through childhood and adolescence. In addition to an effect on hearing loss, treatment provided more rapid resolution of hepatitis, when present, and improved short-term growth in weight and head circumference and developmental milestones.^{358,359} Reversible neutropenia was encountered in 63% of treated infants, and 2% developed reversible and mild drug-associated hepatitis, but otherwise the antiviral treatment was well tolerated.

Valganciclovir treatment for 6 weeks versus 6 months was evaluated in another randomized clinical trial of newborns with symptomatic congenital CMV infection, with and without central nervous system involvement, expanding both the clinical phenotype treated and the duration of antiviral treatment administered to the infants.²⁷³ In this clinical trial, 6 months of oral valganciclovir administered at a dose of 16 mg/kg per dose every 12 hours provided superior benefit over the shorter 6 weeks' duration of treatment, and was more easily administered at home with careful outpatient monitoring. In this trial, hearing outcomes were improved at 1 year of age, and neurodevelopmental scores on the Bayley Scales of Infant and Toddler Development on the language-composite component and the receptive communication scale were superior in the group treated for 6 months compared with the group treated for 6 weeks. Reversible neutropenia occurred during the first 6 weeks in 19% of the infants treated. Therefore monitoring of blood counts should be done regularly in infants treated with valganciclovir.^{21,225}

Currently, most experts agree that antiviral treatment is indicated in neonates with moderate to severe congenital CMV disease with or without neurologic involvement or eye disease or sensorineural hearing loss (see [Box 159.5](#)). Some experts recommend treatment of all neonates who have symptoms to reduce the risk for late-onset hearing loss and improve neurodevelopmental outcome. For maximum benefit, treatment should begin within the first month of life.^{21,225} The decision to administer antiviral therapy to a neonate with congenital CMV disease remains at the discretion of the clinician and should be based on disease severity and risk factors for sequelae.^{225,460,487,495,533} Short-term antiviral therapy is likely to benefit infants who have multisystem disease with viremia detected by positive CMV quantitative DNA PCR assay, pneumonia, severe or persistent thrombocytopenia, hepatitis, enterocolitis, or active sight-threatening retinitis.²⁴² In these clinical

circumstances, a reduction in viral load should improve the infant's clinical condition and resolve end-organ disease. However, the sustained effect beyond 1 year of life of short-term treatment on long-term sequelae, such as hearing loss and neurodevelopmental disabilities, is not clear at this time and requires long-term follow-up studies to confirm this benefit.⁸⁴ A 6 months' duration or longer of therapy with an oral antiviral agent such as valganciclovir may improve outcomes and reduce the development of long-term sequelae, including hearing loss, in these infants.^{23,495,533} Anecdotal reports and phase I pharmacokinetic and pharmacodynamic studies have demonstrated that valganciclovir oral solution provides plasma concentrations and antiviral effects similar to those levels achievable with use of intravenously administered ganciclovir in neonates, and clinical trials have shown that treatment with 6 months of oral valganciclovir provides benefit to some newborns with symptomatic congenital CMV infection.^{272,336} Clinical trials evaluating the long-term benefits of prolonged treatment for 1 year or more with oral valganciclovir in congenitally infected infants are needed because the effects of congenital CMV infection, especially on hearing loss, may be lifelong and progressive. Case series of children with asymptomatic congenital CMV infection and hearing loss treated with ganciclovir and valganciclovir have reported improvement in hearing loss with treatment.^{228,558} However, routine treatment of newborns with asymptomatic congenital CMV infection with or without congenital hearing loss is not recommended but is considered on an individual basis by some CMV experts.^{21,225,405}

In addition to specific antiviral therapy, management of congenitally infected infants includes supportive care, nutritional and feeding support, and control of seizures. If thrombocytopenia is severe and persistent, platelet transfusions and immune globulin also are of benefit. Long-term management includes careful attention to nutrition to ensure adequate growth because many of these infants may have feeding disorders and disorders of growth. In addition, serial hearing tests to detect progressive or late-onset hearing loss should be performed every 3 to 6 months during the first 3 years of life, and then annually thereafter or when clinical changes occur, probably at least through 18 years of age, if not longer.⁵²⁷ Treatment with hearing aids for sensorineural hearing loss is recommended. Cochlear implants may also benefit children with profound hearing loss caused by CMV. Developmental assessments to evaluate for cognitive and motor disabilities should be done on a regular basis, and physical therapy, occupational therapy, and speech language therapies should be prescribed as needed. Motor and mobility disorders also should be assessed and treated with mobility devices, braces, and if indicated, Botox injections for severe spasticity. Careful orthopedic monitoring for scoliosis and hip displacement is important. Ophthalmologic evaluations to follow up abnormalities present in the neonatal period, such as retinitis, and to monitor for vision-threatening, late-onset sequelae, strabismus, and cortical vision impairment should be performed on a regular basis as well.^{253,533,538}

PREVENTION

Prevention of CMV disease is important because it causes significant morbidity and mortality in a variety of patients. In immunocompromised hosts, it also is associated with the development of other complications, such as opportunistic coinfections and graft rejection in transplant recipients, and it increases resource use in transplant programs. In neonates and infants with primary immune deficiency disorders of T-cell and NK-cell function, or SCID, congenital or acquired CMV infection is sight- and life-threatening.³³⁰ In premature neonates, potentially fatal viral sepsis syndromes can occur. Furthermore, congenital infection is a leading cause of deafness, vision loss, and developmental and motor and mobility disabilities in children. Approaches to the prevention of CMV disease include the use of CMV-seronegative blood products, freeze-thawing or pasteurization of maternal breast milk from CMV-seropositive mothers and donors fed to premature newborns, selection of CMV-seronegative donors for transplant recipients, passive immunoprophylaxis with CMV hyperimmune globulin, prophylactic or preemptive use of antiviral agents, active immunization with a CMV vaccine, and behavioral strategies to reduce exposures to CMV-infected secretions.

Blood Product, Human Milk, and Transplant Donor Selection

Transplant recipients who are CMV seronegative and receive solid-organ or bone marrow or stem cell transplants from CMV-seropositive donors are at significant risk for acquiring symptomatic primary CMV infection (see Box 159.6). Therefore, whenever possible, CMV-seronegative recipients should receive transplants from CMV-seronegative donors, and all blood product transfusions should be from CMV-seronegative donors. CMV-seropositive transplant recipients may also experience CMV infection and disease after transplant.

Infection with CMV in seriously ill CMV-seronegative neonates can be prevented by use of blood products from CMV-seronegative donors or by use of frozen deglycerolized red blood cells.^{76,557} Saline-washed red blood cells also reduce but do not always prevent the acquisition of CMV infection in neonates, even though as many as 90% of the leukocytes can be removed by this method.¹³³ An alternative method of preparing leukocyte-depleted blood, filtration through a cotton-wool filter, appears to prevent posttransfusion acquisition of CMV infection in neonates.¹⁹⁶ Many institutions now provide CMV-seronegative or leukocyte-depleted blood products routinely to all neonates or to all low-birth-weight neonates, as well as other immune compromised infants and children, regardless of the CMV serostatus of the mother.

Ingestion of CMV-positive breast milk by premature infants, especially those of less than 28 weeks' gestation, has been associated with illness. Neonatal units may have protocols to test premature neonates with sepsis syndromes with negative bacterial cultures for evidence of CMV infection, to identify them early and institute antiviral treatment if CMV disease is documented and is clinically severe. Donor selection for CMV-seronegative donors or pretreatment through pasteurization or freeze-thaw cycles of human milk administered to extremely premature infants may reduce the risk for acquisition of CMV-associated disease in these infants.^{95,252,318,360,518,520} Pasteurization of breast milk is also effective but reduces the immunologic and nutritional benefits of human milk. Healthy term infants may receive fresh breast milk from CMV-seropositive mothers and donors.³⁷⁹

Passive Immunoprophylaxis

Although immune globulin, CMV hyperimmune globulin, or CMV-enriched immune globulin should not be used alone for the treatment of established CMV disease in immunocompromised patients, these preparations may be used with antiviral agents to treat CMV disease in selected patients and to prevent the acquisition of serious CMV disease in selected immunocompromised patients. The association of CMV immune globulin administration and acute and long-term clinical outcomes in transplantation has not been well defined, but some studies suggest potential benefit.^{53,175}

Passive immunization remains controversial, however, partly because studies or protocols have used different dosages (100–400 mg/kg) administered at varying intervals (1 week before transplantation and every 1 to 3 weeks after transplantation) for varying times (60–120 days). CMV immune globulin has been shown to decrease the incidence of symptomatic CMV disease from 60% to 21% in CMV-seronegative renal transplant recipients who received a kidney from a CMV-seropositive donor.⁴⁶⁵ CMV immunoprophylaxis also has decreased the incidence of CMV pneumonitis in CMV-seronegative bone marrow transplant recipients who did not receive granulocyte transfusions.^{73,326,409,542} CMV hyperimmune globulin administered to liver transplant recipients has been shown to increase the risk for organ rejection but improves long-term graft and patient survival.¹⁷⁵ In pediatric and adult heart transplant recipients, administration of CMV hyperimmune globulin with or without antiviral prophylaxis is also associated with decreased mortality and graft loss.^{463,464} A clinical trial with a CMV-specific monoclonal antibody specific to CMV gH (MSL-109) did not show benefit in a randomized, placebo-controlled, double-blind study in allogeneic stem cell transplant recipients, nor in infants with congenital CMV infection.⁶⁵

The use of immune globulin preparations (CMV hyperimmune globulin, CMV-enriched immune globulin, and standard human IVIG that may contain high titers of CMV IgG) in pregnant women with primary CMV infections to prevent or to ameliorate CMV infection

in the fetus has been reported, and results were favorable.^{15,16,87,121,346,349,517} CMV immune globulin reduces placental inflammation and thickening, neutralizes virus with high avidity antibodies, and reduces cytokine-mediated cellular immune responses.^{10,11,286} In one case-control study, the severity of neurodevelopmental and hearing disabilities in the infants and children of mothers with primary CMV infection who received CMV immune globulin was less compared with those who did not receive CMV immune globulin.³⁴⁷ However, despite these promising results, definitive recommendations for the routine clinical use of CMV immune globulin immunoprophylaxis in women experiencing primary CMV infection during pregnancy to reduce transmission of CMV to the fetus, or to treat or ameliorate in utero CMV disease in the fetus, await results of randomized clinical trials.^{22,334,346,349,393,405}

Prophylaxis and Early Preemptive Therapy With Antiviral Agents

The prophylactic use of antiviral agents in transplant recipients reduces the incidence of serious CMV disease.¹⁵⁹ However, no regimen has been shown to completely prevent the acquisition of CMV infection or disease in recipients of all types of transplants.³⁷⁹

Acyclovir is used by some clinicians as prophylaxis for CMV disease in organ transplant recipients, despite evidence that acyclovir is inactive against most strains of CMV and that CMV disease occurs despite such prophylaxis.⁴⁵⁹ In one study, intravenous administration of acyclovir 500 mg/m² of body surface area per dose every 8 hours for 5 days before and 30 days after transplantation to CMV-seropositive bone marrow transplant recipients appeared to reduce the incidence of CMV disease.³²⁷ High-dose oral acyclovir administered 1 day before and for 12 weeks after transplantation also has been shown to reduce the incidence of CMV disease and infection in renal transplant recipients.⁴⁵

The prophylactic administration of human leukocyte interferon- α has been shown to reduce the incidence of severe CMV disease in renal transplant recipients, but it has no apparent benefit in bone marrow transplant recipients, and it is not used routinely in any patient population.^{106,229,234,412}

The prophylactic use of intravenous ganciclovir and oral valganciclovir in solid-organ and bone marrow and stem cell transplant recipients at high risk for acquiring serious CMV disease is now routine and favored over preemptive treatment.^{159,268,315} Prophylaxis treatment regimens vary, however, and it is difficult to make recommendations about which regimen is best. Most solid-organ transplant recipients appear to benefit from intravenous ganciclovir 5 to 10 mg/kg per day administered once or twice daily for 2 to 6 weeks after transplantation, usually followed by continuing antiviral prophylaxis with a reduced dose of ganciclovir or with orally administered valganciclovir.^{37,507} Administration of a short 2-week course of ganciclovir near the time of transplantation, without continuing antiviral prophylaxis, does not appear to reduce significantly the incidence of CMV disease in most solid-organ transplant recipients studied.^{37,507} Antiviral prophylaxis not only reduces the risk for serious CMV disease but also improves solid-organ graft survival and overall patient survival.¹⁵⁹ A duration of prophylaxis with oral valganciclovir extended to 200 days compared with 100 days after transplantation appears to significantly reduce the incidence of CMV disease. However, delayed-onset CMV disease may still occur, and antiviral resistance may emerge in some patients.^{268,315}

IVIG or CMV hyperimmune or CMV-enriched immune globulin, when it is given with a prophylactic antiviral agent in solid-organ recipients, improves allograft and patient survival. In bone marrow transplant recipients, the administration of ganciclovir prophylaxis after marrow engraftment reduces CMV disease. In addition, some ganciclovir-treated bone marrow transplant recipients may experience prolonged neutropenia.²⁰³ Even though most transplantation centers have adopted prophylaxis strategies with antiviral agents and CMV hyperimmune globulin to reduce the risk for CMV infection and disease, some experts believe the strategy of preemptive antiviral therapy has certain advantages over strategies that either treat only patients with overt clinical disease or administer prophylactic antiviral agents to many patients at risk, only a few of whom appear to benefit.¹⁹⁴ In addition, preemptive or very early antiviral treatment strategies include viral surveillance of blood, urine, and respiratory samples. Viral surveillance of these samples

can be by standard viral culture, viral antigen detection, viral nucleic acid detection by qualitative or quantitative PCR assay, or a combination of these tests. Detection of CMV viremia, or rising quantitative CMV DNA PCR levels, and culture-positive or PCR-positive BAL samples have correlated with the development of serious CMV disease in transplant recipients.⁸¹ In bone marrow, stem cell, and solid-organ transplant recipients, early intervention with intravenous ganciclovir therapy at the time of positive CMV surveillance cultures is beneficial.^{203,449,461} Another approach to preemptive therapy that is currently not practiced routinely and that does not entail viral surveillance techniques is to administer an antiviral agent, such as ganciclovir, only during times of rejection, when CMV reactivation is likely to occur. This approach has been modestly successful in high-risk renal transplant recipients.²²⁷ Simultaneous virologic and immunologic follow-up is the best approach for monitoring CMV infection in transplant recipients. Lack of immune reconstitution or presence of graft rejection or graft-versus-host disease usually heralds repeated episodes of recurrent or persistent CMV infection or disease, requiring multiple or prolonged courses of antiviral and immune globulin therapy.¹⁹⁴ Antiviral resistance to single or multiple agents may occur in these high-risk patients and has been increasingly recognized as a significant problem.¹⁰⁰

In pregnancy, maternal administration of valacyclovir in mothers whose fetus has symptomatic intrauterine CMV infection has been shown to reduce CMV viral load, but not to have direct benefit for the fetus.^{247,405,406} It is not routinely recommended but may be evaluated soon in clinical trials.⁴⁶⁶

Active Immunization

Prevention of acquisition of CMV disease through active immunization is a priority for the 21st century.^{447,485} Universal vaccination of adolescent females to protect their future children against congenital CMV infection has been determined to be cost effective, if a CMV vaccine with at least 61% efficacy is available.¹³⁹ In addition to pregnant women and their fetuses, transplant recipients will benefit greatly if a safe, effective CMV vaccine becomes widely available.^{29,258,443,447} The ideal CMV vaccine should be safe, effective, immunogenic, and cost effective. It should prevent the development of primary CMV infection without causing chronic persistent infection. The vaccine also should not be capable of infecting the fetus, and it should not be oncogenic. However, because the optimal composition and strategy for an ideal CMV vaccine that would be licensed for clinical use remains to be discovered, research continues in animal models and human clinical trials.^{58,199,209,444,447}

In 1975, Plotkin and associates³⁹⁰ characterized and reported a candidate CMV vaccine strain, Towne 125, that was isolated originally from the urine of a congenitally infected infant named Towne. Since then, more than 500 subjects, including renal transplant recipients and healthy adult male and female volunteers, received the investigational Towne 125 vaccine.^{97,177,258,388-390,392,483} Studies of these subjects showed that Towne 125 is attenuated and relatively safe and that it induces humoral and cellular immunity in both healthy and immunosuppressed subjects.

The Towne 125 vaccine also appeared to be protective in a randomized, placebo-controlled study of 91 immunosuppressed renal transplant recipients.³⁸⁹ In this study, 30 CMV-seronegative vaccine recipients received a kidney from a CMV-seropositive donor, and the incidence of severe CMV disease was significantly lower in the vaccine group than in the placebo group. However, the CMV infection rate did not differ significantly between the groups, and members of both groups experienced mild to moderate CMV disease. Subsequent studies have confirmed that CMV-seronegative renal transplant recipients who receive a live, attenuated CMV vaccine are more resistant to serious CMV disease.³⁹¹ Another vaccine strategy investigated was the development of mutant hybrid strains of CMV that combine the safety of the Towne strain with the more virulent and potentially more immunogenic Toledo strain. Early clinical trials demonstrated enhanced immunogenicity but possibly also enhanced virulence.^{12,387,490} Other investigators have evaluated subunit vaccines for CMV that contain purified glycoprotein B (gB) complexed with a powerful adjuvant—alphavirus replicon particle

vaccines and live, attenuated CMV vaccines.^{78,166,371,490} A CMV gB vaccine with MF59 adjuvant recent showed vaccine efficacy of 50% in adult women and provided proof that vaccination has the potential to decrease maternal and congenital CMV infection.^{377,369} However, a similar vaccine, when administered to CMV-seronegative adolescent girls between 12 and 17 years of age, was safe and immunogenic but had an efficacy of only 45%.⁵⁹ The cellular immune system has been targeted by “DNA vaccines” that encode gB and appear to induce protective cellular immunity against CMV.³²² Also, the human CMV gH/gL/UL128/UL130/UL131A pentameric complex has been shown to elicit potentially neutralizing antibodies and is currently under research and development as a possible vaccine candidate.⁵³¹ Finally, adoptive immunotherapy with sensitized T cells has shown promising results for prevention of CMV infection and disease in transplant recipients and is currently being evaluated in clinical trials.^{224,445}

Behavioral Strategies to Prevent Primary Cytomegalovirus Infection in Pregnancy

With the current complexities associated with the development of a CMV vaccine and the challenges of administering effective antiviral therapy, an alternative practical option for prevention of CMV infection during pregnancy and other high-risk times of life is education to increase public awareness about CMV and its modes of transmission.^{101,132,138,208,249,417,430,562} Surveys have documented that knowledge about CMV around the world is low.³¹⁰ Most studies have shown that less than 20% of responders to CMV knowledge surveys have heard of CMV. For example, approximately 7% of men and 13% of women in one study from the 2010 HealthStyles survey had even heard of CMV, even though it is considered a common viral infection.^{93,431} Surveys of a variety of groups confirm broad lack of knowledge about CMV in pregnancy and the newborn.^{36,61,155,396,499,537,545} Educational materials are available from clinicians, from public health and university websites (e.g., Centers for Disease Control and Prevention: www.cdc.gov/cmrv; Baylor College of Medicine: www.bcm.edu/pedi/infect/cmrv; and National CMV Foundation www.nationacmv.org), and from nonprofit organizations and social media websites. These sites provide factual information to promote CMV awareness and guidelines for reducing the risk for CMV transmission to pregnant women, women of childbearing age, and other susceptible individuals.⁴³⁰ Reliable, relatively inexpensive serologic evaluation is available, and some experts recommend that all women contemplating pregnancy should know their CMV serologic status, although it is not routine obstetrical practice to do so.^{22,405} In addition, because epidemiologic studies have shown a major source of CMV infection to be close contact with young children, women who are pregnant, especially women who are known to be CMV seronegative, should be aware that a high percentage of young children are infected actively with CMV and that while pregnant they should exercise good hygienic practices when in close contact with young children, especially those who attend child care centers or are known to have an active CMV infection.^{90,93,120,372} Studies from the United States and Europe have shown that the incidence of child-to-parent transmission of CMV may be reduced by interventions that identify susceptible pregnant women and educate them about increasing protective behaviors when around young toddlers who are likely to be actively shedding CMV in their saliva and urine, such as hand washing after all wet and dirty diaper changes and after wiping tears and nasopharyngeal mucus and decreasing risky behavior for acquiring CMV, such as kissing on or near the mouth and sharing food or sharing eating utensils or cups for drinking.^{7,11,120,174} Many experts recommend women of childbearing age should know about CMV and practice recommended hygienic precautions during pregnancy.^{90,120,138,208,405,406} Studies have shown that these CMV awareness and prevention precautions, as a “CMV knowledge vaccine,” are readily accepted and easily implemented by women in the home.⁴⁹⁹ In addition, CMV can be transmitted from husband to wife, and if the spouse or partner experiences a CMV mononucleosis syndrome, a CMV-seronegative woman may wish to consider avoiding pregnancy for an individualized period of time.¹³⁵

Given the proven lack of CMV awareness in women of childbearing age and in the medical community serving women and children, CMV can be considered “the most common virus most people have never

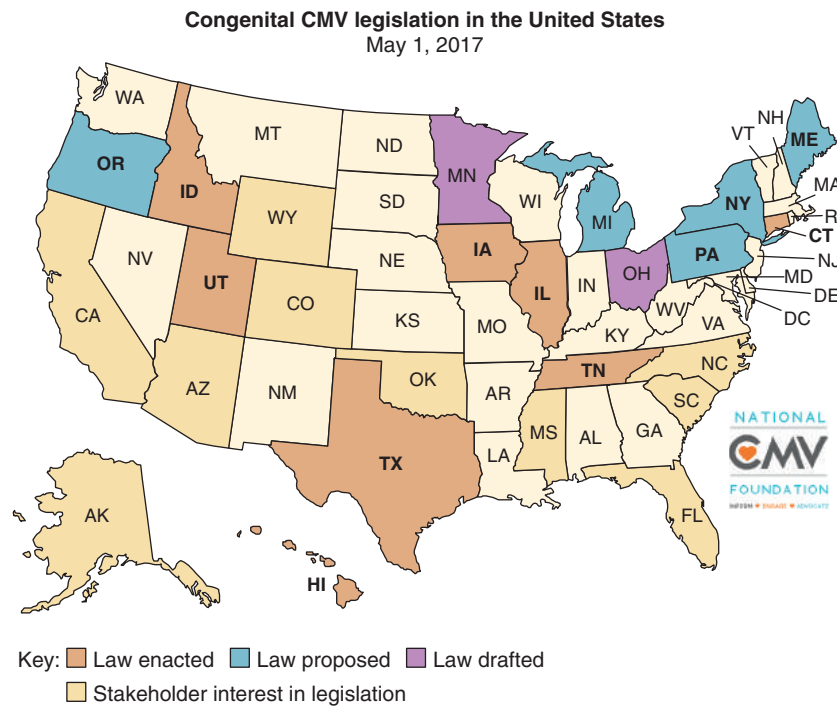

FIG. 159.7 Map of the United States showing states with cytomegalovirus (CMV) legislation enacted, proposed, or in discussion as of May 2017. Addressing CMV awareness and education for pregnant women and health care workers and newborn testing for congenital CMV through public policy can provide greater access to resources to combat the public health problem of congenital CMV. (Courtesy National CMV Foundation; [www.nationalcmv.org.](http://www.nationalcmv.org/))

heard of.” Many states in the United States and many countries around the world have now adopted CMV education and CMV testing laws and policies directing their public health departments to provide CMV educational materials to pregnant women and providing for CMV-targeted testing laws for congenital CMV infection for newborns who fail their newborn hearing screens^{225,550} (Fig. 159.7).

Epstein-Barr Virus

Luis A. Castagnini • Charles T. Leach

Epstein-Barr virus (EBV) is an extremely common herpesvirus that is the etiologic agent of classic infectious mononucleosis (IM).⁵⁹⁶ Evidence continues to mount that the virus also plays a principal role in the development of certain lymphoproliferative diseases and epithelial malignant neoplasms. Its ability to remain in a dormant (latent) state after infection allows reactivation and recurrence of disease, especially under immunosuppressive conditions. Unfortunately, antiviral agents have little effect on EBV-associated diseases, but progress is being made toward improved treatment of the malignant types. Eventually, vaccination may provide protection for those persons at highest risk for development of severe disease manifestations.

This chapter reviews progress in understanding of the immunobiology of EBV and its disease associations. Enhanced understanding of EBV is leading to newer diagnostic methods and improved management of EBV-associated diseases.

HISTORY

Four distinct periods of history are identified with IM and its etiologic agent, EBV^{169,558}: (1) early descriptions of IM, (2) identification of the heterophile antibody test associated with IM, (3) discovery of EBV in Burkitt lymphoma (BL) cells, and (4) association of acute EBV infection with heterophile-positive IM.

Credit for the original description of a disease consistent with what is now called infectious mononucleosis commonly is given to a German physician named Pfeiffer,⁴⁹⁹ who in 1889 described relatively mild illness characterized by fever and lymphadenopathy; later, his report was translated into English.⁴¹⁸ The illness came to be known as Drüsenfieber, or glandular fever. Although some cases of glandular fever were typical of what is now recognized as IM, certain characteristics of this illness, including its predominance in children and familial clustering, did not fit. In England, glandular fever and IM have become synonymous, yet many experts consider glandular fever to be a different illness.

In the early 1900s, numerous case descriptions of illnesses epidemiologically and clinically compatible with IM appeared.^{77,252,306} However, because the illness now recognized as IM had not yet been described and these illnesses were suggestive of leukemia, most of them were reported erroneously as acute leukemia with spontaneous cure. Although the term *infectious mononucleosis* was used first in one of these case reports,³⁰⁶ the illness was not distinguished from leukemia until Sprunt and Evans published their landmark paper in 1920.⁵⁸⁷ These authors described a series of patients with clinical syndromes consistent with typical IM, including classic hematologic findings. A subsequent report by Downey and McKinlay provided a more detailed description of the hematologic manifestations.¹⁴⁷

Although most cases of IM could be identified by hematologic and clinical findings, not until a specific serologic test was identified in 1932 could classic IM be better defined. In the course of investigating

heterophile antibodies in serum from patients with rheumatic fever and other diseases, Paul and Bunnell⁴⁸⁹ noted high titers of heterophile antibodies in serum from a control patient. Further investigation revealed that the control patient was a medical student with IM. Evaluation of sera from three other patients confirmed the presence of high titers of heterophile antibodies during acute IM. Over the next few decades, extensive research continued in a quest to identify the agent responsible for IM. However, no organisms could be cultivated from patients with IM, and attempts at transmitting disease to animals were unsuccessful.

In 1958, Dennis Burkitt, an English surgeon, described 38 cases of “round-cell sarcoma” developing in children and adolescents living in one region of Uganda, Africa.⁷⁵ The tumors were later determined to be lymphomas, not sarcomas. After a seminar at Middlesex Hospital, London, wherein Burkitt described his findings regarding the new tumor in Ugandan children, he met a pathologist, M.A. Epstein, and a collaboration was established.¹ Shipments of lymphoma tissues began appearing in Epstein’s laboratory, and eventually Epstein and a lab assistant (B. Achong)¹⁶¹ successfully cultivated and evaluated tumor cells by electron microscopy. Particles were noted with ultrastructural characteristics similar to those of herpes simplex virus (HSV), which had been described a few years earlier. Further work established this virus as the fourth human herpesvirus (after HSV-1, HSV-2, and cytomegalovirus [CMV]).

The association between this new herpesvirus and IM was noted serendipitously in 1968 when an IM-like illness developed in a technician working in the laboratory of Gertrude and Werner Henle at Children’s Hospital of Philadelphia.²⁷² Stored, preillness serum from this technician contained neither heterophil nor EBV antibodies, but both heterophil and EBV antibodies appeared 6 days after the onset of symptoms. In addition, virus was cultivated from the technician’s peripheral white blood cells. Subsequent testing of serial specimens from other patients with IM also demonstrated seroconversion to EBV in all cases. This work as well as studies from Yale University,^{172,458} among others, firmly established EBV as the cause of IM. Investigators subsequently showed that EBV has the capacity to transform (immortalize) human B lymphocytes in vitro, which allows the derivation of EBV-transformed B-lymphoblastoid cell lines capable of being propagated indefinitely in tissue culture.^{267,506}

VIROLOGY

EBV is in the order Herpesvirales, family Herpesviridae, subfamily Gammaherpesvirinae, and genus *Lymphocryptovirus*. Its closest relative, human herpesvirus 8 (also known as Kaposi sarcoma–associated herpesvirus), is also a gammaherpesvirus, in a separate genus. The taxonomic name for EBV was recently changed from human herpesvirus type 4 to human gammaherpesvirus 4.¹³⁵ Although the original taxonomic

name is used by many bibliographic search services, most scientists and physicians use the historic name.

Structure and Genome⁴¹⁰

The structure of the EBV is typical for a member of the herpesvirus family; it displays an inner core of DNA surrounded by a nucleocapsid, tegument, and envelope.¹⁶² Within the core, which measures approximately 45 nm, exist approximately 184 kilobase pairs (kbp) of double-stranded DNA coding for nearly 100 proteins. The surrounding nucleocapsid displays icosahedral symmetry (162 capsomeres) and measures approximately 100 nm in diameter. Outside the capsid lies the tegument, which is an amorphous substance consisting of numerous proteins common to all human herpesviruses, several proteins specific to the gammaherpesviruses, as well as cell proteins such as actin and β -tubulin, likely involved with reenvolvement.³²⁴ The tegument in turn is surrounded by the viral envelope containing glycoprotein spikes. The complete virion measures approximately 150 to 220 nm.

The sequence of the entire EBV genome was first published in 1984.³⁵ Eleven more EBV genomes were reported through 2015, when Palser et al.⁴⁸¹ provided the complete sequences of an additional 71 genomes and analyzed the 83 cumulative genomes. The structure of EBV is characteristic of all the herpesviruses, with short and long sections of “unique” sequences (U_S and U_L , respectively) separated by a major internal repeat region (IR_L) generally consisting of six to 12 direct repeats of a 3-kbp sequence.¹³⁸ The virus also has numerous other regions of repeated nucleotide sequences, including direct repeat of a 0.5-kbp sequence at its termini.

Molecular Biology

Much of the early information about the molecular biology of EBV comes from laboratory strains derived from BL tumor cell lines (e.g., HR-1)²⁸⁰ and marmoset lymphoid cell lines transformed by viral strains infecting human beings (e.g., B95-8). Sequencing information on 83 complete genomes has recently added to the amount of information available for studying the molecular biology of EBV.⁴⁸¹

Replication

EBV infection of B cells is initiated by attachment of EBV envelope glycoprotein gp350 to a cell surface receptor (CR2, CD21) found primarily on B lymphocytes. It has long been recognized that CD21 is not necessary for B-cell fusion, and recently another B-cell receptor for EBV has been identified: CR1, or CD35.⁴⁶⁸ Fusion of the host B cell first requires assembly of the core fusion machinery, common to all herpesviruses: EBV glycoproteins gB and gH, as well as gL (necessary for the unfolding and transport of gH). This complex then requires activation via interactions with human leukocyte antigen (HLA) class II protein, which is mediated by the binding of gp42 to gH/gL, thus forming the complex gp42/gH/gL. Because epithelial cells do not possess CD21 receptor, an alternative mechanism for fusion exists, involving EBV glycoproteins gH/gL binding to integrins $\alpha v \beta 6$ and $\alpha v \beta 8$.¹⁰⁴ After entering the B lymphocyte, the virus is transported through the cytoplasm and is stripped of its envelope in endocytic vesicles.⁴⁵⁶ Subsequently, the viral genome circularizes and is maintained in the cell nucleus as a multicopy plasmid (or episome).⁴⁰⁵

Epithelial cells recently were conjectured as playing a much larger role in oropharyngeal replication and shedding of EBV, based on biologic data and mathematical reasoning.²⁴⁸ The initial and predominantly replicative (lytic) EBV infection probably occurs in epithelial cells of the oropharynx and adjacent structures,^{577,671} with virus then transmitted to circulating B cells passing through these lymphoepithelial tissues. Although lytic genes may be found in EBV-associated tumors (e.g., posttransplant lymphoproliferative disease [PTLD]),⁴⁴³ the overall proportion of replicating cells is far surpassed by latently infected B cells. In contrast, after infection of epithelial cells occurs, active replication develops and leads to lysis and death of the cell. Alternating replication of viral glycoproteins in B cells and epithelial cells appears to modify the viral tropism, allowing virus from replicating B cells to infect epithelial cells more efficiently, and vice versa.⁶⁴ There are also data suggesting that monocytes may play an important role as a reservoir for EBV and could provide an important link for the transfer of virus from B cells

to the oral epithelium.⁶³⁴ Proteins synthesized during viral replication are important for viral gene regulation, replication of the genome, production of mature particles, and modulation of the immune system.

Latency

Latently infected B cells are the primary reservoir of EBV in the body. In a typical healthy EBV-seropositive adult, 1 to 50 per million B cells are infected with EBV, and this condition remains relatively constant for many years.³¹ Although more than 80 gene products may be expressed during active viral replication, only a limited number are expressed during viral latency. This is one method by which the virus limits cytotoxic T-cell recognition of EBV-infected cells. The EBV gene products that may be expressed during latency include six nuclear proteins (EBV nuclear antigens [EBNAs] 1, 2, 3A, 3B, and 3C and a leader protein [EBNA-LP]); three membrane proteins (latent membrane proteins [LMPs] 1, 2A, and 2B); two small, nonpolyadenylated (noncoding) RNA molecules (EBV-encoded RNAs [EBERs] 1 and 2); the Bam H1A rightward transcripts (BARTs); and microRNAs (miRNAs).

On the basis of in vitro genetic and somatic cell hybrid experiments, three different patterns of latent gene expression can exist in EBV-infected cells from patients with EBV-associated disease.^{138,336,366,410,605,623,680,686} Type I latency, exemplified by cells derived from BL and gastric carcinoma, exhibits a limited repertoire of genes consisting of EBNA-1, EBERs, BARTs, and BART miRNAs. Type II latency typically is observed in cells derived from EBV-positive Hodgkin lymphoma (HL), nasopharyngeal carcinoma (NPC), and T-cell lymphomas. Besides EBNA-1, EBERs, BARTs, and BART miRNAs, these cells also express all three latent membrane proteins (LMP-1, LMP-2A, and LMP-2B). Lymphoblastoid cell lines as well as tissues from patients with IM and PTLD display the broadest pattern of latent gene expression (type III), wherein all genes associated with latency are expressed^{366,555,620,685} as well as both BART and BHRF1 miRNAs.³⁶² Type 0 latency occurs within circulating EBV-infected memory B cells from healthy persons, wherein only EBERs and BARTs are expressed.⁴¹⁰ Although these latency expression pattern categories may be useful for histopathologic characterization, significant heterogeneity among histopathologically similar tumors can occur.

A brief description of latency-associated EBV genes follows.

EBNA

EBNA-1 is required for replication and maintenance of EBV episomal DNA in latently infected cells.³⁶⁶ It also interacts with various viral promoters in regulating transcription of the EBNAs (including itself) as well as LMP-1. As mentioned previously, amino acid repeat structures in the EBNA-1 protein protect it from proteosomal degradation, thereby stabilizing protein levels and possibly preventing presentation by major histocompatibility complex class I molecules.³⁹⁵ The protein's contribution to the transformation of B cells was recently reported, and evidence continues to accumulate supporting EBNA-1's role in oncogenesis.¹⁹³ EBNA-2 resides in the cellular nucleoplasm, chromatin, and nuclear matrix. It is clearly a viral oncogene that is essential for cellular transformation. The ability of type 1 EBV genotypes (discussed in the section on [EBV genome variation](#)) to more efficiently transform B cells is attributable to differences in the EBNA-1 region of the genome. It transcriptionally activates several viral genes (e.g., LMP-1, LMP-2A) and cellular genes (e.g., CD21 and CD23) by its interaction with the DNA-binding protein RBP-J κ (J κ recombination-binding protein).²⁷² All three EBNA-3 proteins (A, B, and C) are transcriptional regulators of key cellular and viral promoters, but only 3A and 3C have proved to be indispensable for in vitro B-cell transformation.⁶²⁷ The primary regulatory functions of EBNA-3 proteins, like those of EBNA-2, occur through interactions with RBP-J κ .⁵³⁴ Moreover, EBNA-3C is able to overcome the arrest of the retinoblastoma (Rb) gene cell cycle and increases expression of LMP-1.⁴⁰² The exact mechanistic contribution of EBNA-LP (also called EBNA-5) to B-cell immortalization is not well understood. Although EBNA-LP is not required for transformation of B cells, the absence of EBNA-LP drastically reduces the efficiency of transformation.⁴²² EBNA-LP possibly contributes to immortalization by enhancing EBNA-2-mediated transcriptional activation of the LMP-1 gene.⁴⁹³ Also, previous studies have demonstrated that EBNA-LP

cooperates with EBNA-2 in driving cells into the G₁ cell cycle phase by binding and inactivating the tumor suppressors Rb and p53.⁶⁰⁹

Latent Membrane Proteins

Like EBNA-2, LMP-1 (a viral oncogene) is essential for EBV transformation of B cells and appears to be the main transforming protein of EBV.⁸⁷ LMP-1 displays pleiotropic effects when it is expressed in EBV-infected cells. Most prominently, LMP-1 mimics the CD40 B-cell receptor, which plays a key role in the activation and differentiation of B cells.³⁵³ The protein also induces expression of antiapoptosis genes (e.g., BCL-2 and A20) as well as activation and adhesion of B cells.⁵⁵⁸ LMP-2 consists of two transmembrane proteins: LMP-2A contains two intracytoplasmic domains (at the amino and carboxy termini) and 12 integral membrane domains; LMP-2B differs by the lack of the amino-terminal cytoplasmic domain. LMP-2 generally is recognized as a modifier of normal B-cell development, promoting maintenance of viral latency.⁶⁸⁶ LMP-2A mimics the B-cell receptor and alters normal B-cell signal transduction by inducing a range of genes involved in cell cycle induction, inhibition of apoptosis, and suppression of cell-mediated immunity. Functions of LMP-2B are less well described, due to lack of any specific antibody reagents. Nevertheless, it appears that its main role is to serve as a negative regulator of LMP-2A.⁵⁴⁴

EBERs

These two small nonpolyadenylated (noncoding) RNAs are the most abundant viral transcripts, consistently found in latently infected EBV cells (approximately 10⁷ copies per cell) and, indeed, serve as important diagnostic tools through the use of in situ hybridization (see later section on diagnosis, EBV nucleic acid). Studies indicate that EBERs may play important roles in viral persistence and oncogenesis for some tumors. However, conflicting laboratory results have made it difficult to confirm any specific roles for EBERs, with further careful studies to settle these discrepancies anticipated.⁴¹⁰

BHRF1 and BALF1

BHRF1 is a virally-coded homologue of bcl-2 (an antiapoptosis protein), and can protect EBV-infected cells from apoptosis. BALF1 also is antiapoptotic, and recent studies indicate that it can enhance tumor formation as well as potentiate metastases.²⁹⁵

BARTs

These consist of a family of differentially spliced RNAs, first identified in NPC and later found in other EBV-associated malignant diseases.⁵⁸⁰ BART mRNAs are found at low levels in all forms of latent and lytic EBV infections. Four proteins are encoded by BART mRNAs: BARF0, RK- BARF0, A73, and RPMS1. However, none of these proteins have been identified in EBV-infected cells.

MicroRNAs

MicroRNAs (miRNAs) are recently discovered, small (19-24 nucleotides) noncoding RNAs that posttranscriptionally regulate mRNA translation.³⁶⁹ The EBV genome produces at least 44 mature miRNAs, located in three clusters (one adjacent to the BHRF1 gene, and two within BART transcripts).³⁶² Research on EBV miRNAs is in its infancy, yet several key targets have been identified. Studies to date indicate that most of EBV's miRNAs are involved in sustaining latent infected cells. Other functions include contributing to the transformation to B lymphocyte latency, regulation of apoptosis, and immune evasion.^{180,362}

Transformation

In vitro, resting human B cells infected with EBV develop into lymphoblastoid cell lines. These cells are described as immortalized or transformed because instead of following one of two normal pathways (differentiation or apoptosis [programmed cell death]), they proliferate continuously.³⁴⁰ Current evidence suggests that EBV proteins coded by six latency-associated genes (described previously) are important for this cell transformation process: EBNA-2 and LMP-1 are absolutely essential; EBNA-1, EBNA-3A, EBNA-3C, and EBNA-LP also play critical roles.⁴¹⁰ The remaining latency-associated viral gene products, although not essential for transformation, are involved in the initiation and maintenance of cell transformation.

EBV generally transforms relatively mature B lymphocytes, secreting a complete immunoglobulin product (heavy chain plus light chain).^{70,461} EBV also is capable of infecting and transforming B cells in earlier stages of development (e.g., pre-B cells [producing only μ chains] and lymphoid precursors lacking immunoglobulin gene rearrangement)^{198,199,340,350}; mature plasma cells cannot be infected by EBV. Tumor cells and cell lines from BLs are B cells that generally express small amounts of immunoglobulin, which may be detected as surface immunoglobulin molecules, cytoplasmic/secreted molecules, or both. The major heavy-chain isotype expressed by Burkitt tumors appears to be μ chain (IgM), although other isotypes can be observed.⁴⁶¹ Similarly, the EBV-infected cells observed in the blood of persons with mononucleosis and the tumor cells found in immunodeficient hosts with EBV-associated lymphoproliferative diseases and lymphoma are B lymphocytes; these EBV-infected cell populations may include cells producing any of the major classes of human immunoglobulin (IgG, IgA, or IgM).^{70,461,535,536} EBV-related malignant lymphoproliferations in immunosuppressed patients may be polyclonal, oligoclonal, or monoclonal; the lymphoproliferations probably are polyclonal at first but eventually progress to monoclonality.¹³⁹ BLs, on the other hand, always appear to be monoclonal at initial evaluation.^{48,461}

EBV Genome Variation

Two genotypes of EBV (EBV-1 and EBV-2, or type A and type B) were first identified in the 1980s on the basis of marked differences in several genes, including EBNA 2 and EBNA 3A, 3B, and 3C.^{545,552} EBV types 1 and 2 have only 70% DNA sequence homology in the EBNA2 gene, whereas EBV isolates with the same genotype share more than 95% of sequences in this region. Subsequent studies identified geographic differences in the prevalence of these genotypes.^{98,176,179} Recent analysis of 83 sequenced EBV genomes has indicated that there is diversity throughout the genome, but the highest degree of diversity occurs among the latency genes, particularly EBNA2 and the EBNA3 family,⁴⁸¹ with the type 1 and type 2 classification being the major form of EBV variation.⁴⁸¹

EBV-1 is the most common genotype worldwide and is the main genotype in regions with predominantly Caucasian or Asian populations. EBV-2 can only be found at rates comparable to EBV-1 in equatorial Africa, Papua New Guinea, and Alaska. Most EBV-infected persons harbor one genotype, but coinfections can occur. There is some evidence that immunocompromised populations are coinfecting at higher rates.^{122,123,164,480,677}

Besides DNA sequence variability, EBV genotypes also differ in certain in vitro biologic properties. Most notably, type 1 viruses display more efficient transformation of B lymphocytes as well as a faster growth rate.⁵³⁰ EBV-2, in contrast to EBV-1, can spontaneously enter the lytic cycle when incubated with B lymphocytes.⁷³

Early studies suggested that healthy and immune-compromised patients harbored only one or two EBV isolates (or strains). Since then, more powerful methods have made it possible to distinguish EBV isolates with relatively minor differences in DNA sequence. Subsequent studies have revealed that multiple infections can exist in healthy as well as immunosuppressed patients.^{105,159,370,589,649} Some studies have demonstrated that multiple strains are typically acquired early in the infection, and that strains generally remain stable over time within each compartment (e.g., mouth, PBMCs, plasma), although there is some degree of movement among compartments.^{370,572} It is important to note that there is neither convincing scientific evidence that a specific EBV genotype or strain is responsible for specific lymphoproliferative diseases, nor such evidence that one causes higher proportions of any recognized EBV-related diseases.^{98,513}

IMMUNOPATHOGENESIS

Infectious Mononucleosis

EBV elicits a wide range of immunologic responses in humans, partly because of its propensity to infect B lymphocytes. In a normal host, immunologic effects are generally believed to be responsible for EBV-associated disease manifestations. Both cellular and humoral immunity develop in response to EBV infection. Detection of humoral antibodies

directed against viral capsid and nuclear proteins is important for establishment of the diagnosis of acute infection. However, the responsibility for effective control of EBV infection lies primarily with the cellular immune system.²²⁶

As discussed earlier, during the incubation period for IM, EBV can be detected in the mouth as early as 1 week prior to disease. Low-level EBV viremia can begin up to 3 weeks prior to onset of symptoms,¹⁵¹ although high blood levels do not appear until near the onset of symptoms. In conjunction with the onset of symptoms, a massive expansion of CD8⁺ T cells ensues. In college students developing primary EBV infection, increased NK cells were observed, in addition to predicted increases in CD8⁺ T cells and EBV viremia.³⁸ Moreover, higher CD8⁺ and NK cell numbers, as well as an increased level of EBV in blood, were all associated with the severity of illness. This challenges the long-held belief that IM symptoms simply resulted from an immunopathologic process primarily involving CD8⁺ T cells. As symptoms abate, the level of EBV in blood also abates, although low-level viremia can extend past 6 months.³⁸ In contrast, high concentrations of virus can remain in saliva for many months.^{38,173}

In adults the proliferation of CD8⁺ T cells causes a temporary inversion of the normal CD4⁺/CD8⁺ T-cell ratio; however, CD8⁺ T-lymphocyte expansion is less marked in children.⁶⁵⁵ After this T-cell response, the number of EBV-infected B cells falls dramatically during the next 4 to 6 weeks to concentrations of approximately one per 1 million circulating B cells.⁵³⁷ During convalescence, HLA-restricted cytotoxic T lymphocytes keep EBV in check, primarily by targeting the latently expressed EBNA-3 protein.⁶¹²

During the acute stages of IM, despite a brisk immune system response to EBV, widespread and extensive impairment in general cell-mediated and humoral immunity also exists. For example, low or absent delayed-type hypersensitivity reactions develop in response to tuberculin and other antigens.^{249,421} In addition, T cells from patients with IM display unusually weak proliferative responses when they are exposed to recall antigens (e.g., *Candida albicans*, tetanus toxoid).^{444,618} Although EBV-specific cytotoxic and suppressor T cells appear during acute infection, the T-cell response is primarily nonspecific and HLA unrestricted.^{361,486,524} Furthermore, a polyclonal humoral response occurs during acute infection with EBV.⁵⁴² Each B cell committed to one isotype continues to produce that isotype after transformation of EBV, thereby leading to secretion of all classes of immunoglobulins, although primarily IgM.^{603,672} In addition, at least 16 EBV proteins and RNAs (e.g., LMP1, LMP2, EBERs) have been identified as suppressing various functions of the immune response.⁴¹⁰

Once primary infection occurs, EBV, like other herpesviruses, is able to persist in a latent state in a human host throughout that person's lifetime. For EBV, the cellular site for latency is the memory B-cell. The ability to remain undetected for the lifetime of its host indicates that EBV exerts some influence on the immune response to prevent its complete eradication. With its large genome, this process of immune system evasion is carried out primarily through the coding of functional homologues of many cellular factors that are involved in cell cycle regulation, signal transduction, and inhibition of programmed cell death (apoptosis).

Epstein-Barr Virus–Associated Tumors

In normal hosts, cellular immune responses are adequate for control and sequestration of EBV-infected cells. However, cellular immune deficiency may allow uncontrolled proliferation of EBV-infected B cells to occur during primary or reactivated (recrudescent) EBV infection. Such an excessive EBV-associated production of B cells may be histologically pleomorphic (such as B-cell lymphoproliferative diseases) or relatively uniform (monomorphic, such as B-cell lymphomas). In organ transplant recipients, no consistent chromosomal translocations are associated with the lymphomas. Many of these lesions regress once immunosuppressive therapy initiated after transplantation is withdrawn.⁶⁸⁵ In rare, severe cases, B cells harboring EBV DNA and expressing EBNA may become disseminated throughout the body as plasmacytoid cells visible on peripheral blood smears and as B-lymphoid cells potentially invading all organs of the body. Life-threatening EBV infections also may be correlated with an overly strong virus-induced T-cell

proliferation that might cause autoaggressive activity, producing hypogammaglobulinemia or other major organ dysfunctions.⁴⁶

The pathogenesis of EBV-associated malignant disorders in some settings may be multifactorial and involve a mixture of virologic, genetic, and environmental factors. NPC, which occurs predominantly in a specific geographic locale, has been linked etiologically with EBV.^{269,283} The identification of epithelial cells as potential targets for EBV infection, thereby allowing a lytic (productive) infection, has strengthened this relationship.⁵⁷⁷ Further studies have revealed that NPC is a monoclonal proliferation that develops subsequent to EBV infection, with EBV gene products required for tumor growth.⁴⁸⁷ However, NPC also clearly has a genetic association, inasmuch as strong linkage to a specific HLA type exists.³⁸⁹ Furthermore, early EBV gene expression can affect profoundly the growth of infected cells, with full malignant potential reached when mutations occur on chromosomes 3 or 9 (presumably affecting tumor suppressor genes).^{296,297} These mutations possibly result from adverse environmental conditions (e.g., exposure to chemical carcinogens, such as the volatile nitrosamines and polycyclic hydrocarbons in salted fish).³²² Furthermore, miRNAs also appear to play a key role in the carcinogenic process.⁴¹³

The EBV genome and expression of EBNA-1 are present in more than 95% of BL cells derived from African patients with BL (endemic BL), with the genome existing as circular episomes. In contrast, only 15% to 30% of cases of nonendemic (or sporadic) BL occurring in Europe and the United States contain EBV DNA.^{299,693} In addition, EBV is present in more than 95% of primary lymphomas of the central nervous system (CNS) in patients with acquired immunodeficiency syndrome (AIDS).⁴¹⁵ BL cells, but not the lymphoid cells found in IM, exhibit characteristic chromosomal alterations associated with enhanced malignant potential. Approximately 90% of BL tumors exhibit a reciprocal translocation involving the long arms of chromosomes 8 and 14, t(8;14); most of the remainder have t(8;2) and t(8;22).^{360,546} These translocations place the *c-myc* oncogene under the control of an immunoglobulin promoter,^{131,617} which results in transcriptional deregulation and overexpression of the *c-myc* oncogene.^{126,384} Malaria is well known to cause chronic B-cell stimulation, providing enhanced opportunities for *c-myc* translocations within germinal centers of lymphatic tissue. Healthy children living in areas with holoendemic malaria may have high viral loads of EBV in peripheral blood, with acute malaria further augmenting the viral load.⁶⁸⁴ In addition, Piriou et al.⁵⁰² demonstrated that infants living in an area of Kenya with year-round malaria exposure acquired EBV at a younger age, compared to controls with less intense malaria exposure (7.28 months vs. 8.39 months, respectively). Furthermore, these infants had higher levels of EBV viremia, indicating poor control of the virus. This further contributes to the hypothesis that early acquisition of EBV is one important step that, when complemented with malaria-induced B-cell proliferation, and *c-myc* gene rearrangement and activation (and possibly other events), eventually leads to endemic BL.¹³⁶

The differential incidence distribution of HL in children throughout the world corresponds with the age at first EBV infection: it increases in adolescence in developed countries and increases in early childhood in developing countries.^{245,325} The association of EBV with HL is based primarily on serologic studies^{392,450} and identification of EBV DNA in H-RS cells (the malignant cells characteristic of HL).^{350,658} Virtually all cases of HL in developing countries are associated with the presence of EBV, whereas the virus is present in 20% to 50% of patients (age <35) with HL in developed countries.³⁴⁹ However, in developed countries, EBV is strongly associated with HL in children younger than 10 years and in tumors displaying the mixed cellularity variant.^{24,296,479} The precise pathogenetic mechanisms for EBV-associated HL are being unraveled, but evidence indicates that HL is primarily a result of chronic inflammation, with EBV (via latency II gene products and RNAs) contributing to the overproduction of various cytokines and chemokines by H-RS cells and the surrounding inflammatory cells.¹⁷⁷

PTLD may develop in organ and bone marrow transplant recipients during the intense immunosuppression that occurs after placement of the graft. PTLDs span a spectrum of lymphoproliferation from polyclonal disease to monoclonal, monomorphic disease that often is difficult to distinguish from typical malignant lymphomas developing in patients

with intact immune systems. No proof exists that an orderly progression leading to malignant lymphoma occurs; however, one model for the pathogenesis of PTLT proposes that defective immune surveillance after transplantation allows polyclonal proliferation of EBV-infected cells displaying a type III latency pattern (similar to that observed in IM).¹¹⁷ Subsequently, genetic mutations at various loci (e.g., *c-myc*, *p53*) may allow progression to full malignant lymphoma.¹³⁹

HISTOPATHOLOGY

Infectious Mononucleosis

Because IM typically is benign and the diagnosis is based primarily on clinical and serologic findings, histopathologic examination of tissues seldom is required.^{126,128,219,608} However, histopathologic information is available on some tissues (e.g., lymph nodes, tonsils, spleen) from unusual cases and from patients requiring surgery.⁶²⁶ For patients in whom lymphoproliferative disease and other serious manifestations of EBV infection develop, a larger amount of information is available from a broader range of tissues.⁴⁴⁴

Lymph nodes are enlarged diffusely during acute IM. On histologic examination, active lymphoid follicles are noted, with lymphoid proliferation extending to the sinuses, blood vessels, trabecula, and capsule.⁴⁴⁴ The capsule remains intact despite substantial hyperplasia. The lymphoid response consists primarily of T and B immunoblasts, typically with a pleomorphic pattern and frequent mitoses indicative of rapid cell turnover.⁶²⁶ Other cells identifiable in lymph node tissues include a substantial number of small lymphocytes, large atypical lymphocytes, plasma cells, histiocytes, and eosinophils. Micronecrosis may be present, although it is less extensive than that observed with herpes lymphadenitis. Tonsillar tissue also contains an active lymphoproliferative response but with more prominent follicles and extensive necrosis.

The spleen is enlarged two to three times its normal weight during acute IM, primarily as a result of hyperplasia of the red pulp. As in the lymph nodes, the cellularity is principally from immunoblasts with substantial pleomorphism. Hemorrhage, primarily subcapsular in location, is identified commonly. The liver typically shows minimal disease; infiltration by lymphocytes and monocytes occurs principally in the portal areas, and possibly minor degenerative changes take place in hepatocytes. Bone marrow may appear relatively normal during IM, but some series have reported hypercellularity and small granulomas.¹²⁸ From the relatively few cases of CNS disease associated with EBV infection, histopathology reveals lymphocytic infiltration of the meninges.¹³ Less common findings include demyelination, degeneration, focal hemorrhage, congestion, and edema.

Epstein-Barr Virus–Associated Malignant Diseases

The most common form of non-Hodgkin lymphoma (NHL) is BL, which consists of sheets of small non-cleaved cells that are histologically uniform. Most arise from a single infected cell (monoclonality). The majority of CNS NHL tumors display large-cell morphology, with virtually all containing monoclonal EBV DNA. In PTLT, a wide range of histologic findings may be noted. At one extreme, one finds benign lymphoid hyperplasia with normal tissue architecture and a pleomorphic response arising from numerous infected cells (polyclonality). At the other end is observed frank malignant lymphoma.¹²⁵ The 2016 WHO classification of lymphoid malignancies recognizes six histologic types of PTLT⁶⁰⁶; polymorphic and monomorphic types of PTLT are the most common in children. Most polymorphic PTLT cases occur less than 1 year after transplantation, and virtually all are linked to EBV; monomorphic PTLT, however, typically presents later and is more heterogeneous, with a slightly lower rate of EBV association. T-cell PTLT is quite rare, occurs very late, and usually is not EBV driven.⁶⁶⁷

HL is unique among cancers, as less than 1% of cells within the tumor are actually neoplastic.³⁴³ HL tissues are characterized by the presence of diffuse inflammatory cell infiltrates admixed with a low level of neoplastic cells: classic Reed-Sternberg cells and mononuclear Hodgkin cells (referred to collectively as H-RS cells). Reed-Sternberg cells are large (15–45 μm), multinucleated cells demonstrated to derive from germinal center-derived B cells.³⁶⁶ These cells exhibit strongly stained nucleoli surrounded by a characteristic clear area resembling a

halo. In the 2016 World Health Organization classification system of lymphoid neoplasms,⁶⁰⁶ HL consists of two main subgroups: nodular lymphocytic-predominant HL and classic HL. Within classic HL are four distinctive histologic categories based on the predominant cell type and characteristics of the background cellularity: (1) lymphocyte rich, (2) nodular sclerosis, (3) mixed cellularity, and (4) lymphocyte depleted. In Western countries, EBV can be identified in approximately 40% of HL tissue specimens; mixed cellularity and lymphocyte-depleted types are associated most strongly with EBV. Children most commonly develop the nodular sclerosing variety.

Of the three histopathologic categories of epithelial tumors in the nasopharynx, the most common form in children is the undifferentiated variety, which is associated most strongly with EBV.²⁹ Examination of these tumors reveals undifferentiated squamous cells, with substantial infiltration by lymphocytes. Malignant cells consistently contain multiple copies of monoclonal EBV DNA within episomes, and several EBV proteins are expressed.¹¹⁰

Other Epstein-Barr Virus–Associated Diseases

The tissues involved in hemophagocytic lymphohistiocytosis typically include the bone marrow, spleen, liver, and lymph nodes, but the skin or brain may be affected as well.¹⁸⁶ Early in HLH that is secondary to EBV (or other infectious agents), bone marrow is typically normal; later, abnormalities such as hypocellularity or hypercellularity can be noted.²⁰⁹ Activated macrophages (or histiocytes) appearing “stuffed” are observed engulfing all bone marrow cellular elements or their precursors or fragments, including erythrocytes, leukocytes, and platelets.^{186,533,668} Immunostaining for CD163, a receptor whose upregulation can promote hemophagocytosis, may be useful.²⁰⁹ Tissues affected by oral hairy leukoplakia (predominantly in adult patients with AIDS)¹⁶⁰ reveal keratin or parakeratin projections, mild hyperparakeratosis and acanthosis, ballooning and hyperplasia of the prickle cell layer, and only a sparse inflammatory cell infiltrate in the subepithelial connective tissue.²³³ The principal histologic findings in pulmonary tissue from children infected with human immunodeficiency virus (HIV) and having lymphocytic interstitial pneumonitis are lymphoid nodules and diffuse infiltration of the alveolar septa and peribronchiolar regions by lymphocytic cells, including lymphocytes, plasma cells, plasmacytoid lymphocytes, and immunoblasts.²¹ Some lymphoid nodules may be observed as well. The infiltrating lymphocytes consist of B cells and T cells.³³⁴ Necrosis is not observed, and blood vessels are not affected.

EPIDEMIOLOGY

Seroprevalence

Epidemiologic studies of EBV were stimulated by development of reagents for detection of specific anti-EBV antibodies in serum in the mid-1960s. Specifically, tests detecting antibodies to VCA (long-lasting, early in infection) and EA (short duration, early in infection) were used. Henle and Henle,²⁶⁸ using an immunofluorescence method, first noted a high prevalence of EBV VCA antibodies (100%) in patients with BL, but they also discovered a relatively high prevalence (85%) in normal adults. Subsequent studies, published between 1969 and 1975, in American^{210,271,508,595,601} and British⁴⁹⁵ populations, established that 80% to 95% of adults have serologic evidence of past EBV infection, with most infections occurring during infancy and childhood. More recently, information from antibody testing of a sampling of the US population (the NHANES study—see below) revealed an EBV antibody prevalence of 89% for 18- and 19-year-olds.

The age at initial (primary) infection varies markedly in different cultural and socioeconomic settings, a fact that has great pertinence to manifestations of disease associated with primary infection. Recently, EBV seroepidemiologic data were published on a statistically representative sample of the U.S. population (National Health and Nutrition Examination Survey [NHANES]),⁸⁹ in the age range of 6 to 19 years.⁴⁰ Sera collected during four 2-year time periods, between 2003 and 2010, were tested for EBV VCA IgG antibodies. EBV antibody prevalence in the most recent population group (2009–10) showed a significant increase with increasing age: 50% (ages 6–8 years), 55% (9–11 years), 59% (12–14 years), 69% (15–17 years), and 89% (18–19 years). Interestingly, over

the course of the study, a significant decline in seroprevalence was noted for the combined age groups (i.e., age 6–19 years): 72% (in 2003) and 65% in 2010 ($P = .027$).⁴⁰ Non-Hispanic whites had a lower EBV antibody prevalence (64%) compared to Mexican Americans and non-Hispanic blacks (88% each). Finally, a lower EBV antibody prevalence was observed in each race/ethnicity group with respect to health insurance coverage, increased education, and less household crowding.⁴⁰

In developing countries, EBV infection occurs at an earlier age than in developed countries, with recent studies demonstrating EBV infections in more than 50% of 12-month-old infants.^{502,579} HIV-infected infants from Africa have even higher rates of EBV infection.⁵⁷⁹ As in developed countries, EBV prevalence in developing countries also varies according to race/ethnicity, geography, and specific socioeconomic factors.³¹⁶

In developing countries, most children with primary EBV infection have clinically silent or mild disease.^{55,189,575,601} In developed countries such as the United States, primary infection with EBV typically is delayed. For reasons that remain largely unclear, primary infection in older age groups (e.g., ages 10–30 years) in developed countries is more likely to induce clinical symptoms—most often a mononucleosis syndrome.⁹² Possible reasons for this occurrence were recently suggested by Balfour et al.,³⁷ including (1) lack of recognition of IM in preadolescent children; (2) a higher inoculum of virus via “deep kissing” in adolescents/young adults (a known risk factor for IM)^{39,284}; and (3) certain NK T cells identified in the blood of children, but not adolescents/adults, which play an important role in controlling early EBV infection.³⁰ A recent prospective study involving students from one US university demonstrated that 77% of those acquiring primary EBV infection developed classic IM.³⁹

Incidence

The incidence of IM from population-based studies ranges between 50 and 100 cases per 100,000 population.^{172,265,266} These studies indicate that the highest incidence rates for IM occur in the age group of 15 to 19 years. The incidence of IM on a college campus was 14.4 cases per 100 person-years at risk.³⁹ Early reports of higher rates of IM in whites versus other racial/ethnic groups^{82,265} are most likely explained by the higher prevalence of EBV antibodies in some nonwhite racial/ethnic groups, including non-Hispanic blacks and Mexican Americans.⁴⁰ Since IM is a manifestation of primary EBV infection, a larger proportion of nonwhite populations are already EBV positive and therefore unable to develop IM.³⁹ No consistent data support any seasonality associated with EBV infections. Although the infection has no clear-cut predilection for males or females, one study noted IM developing in males at a slightly higher rate than in females.²⁶⁶

Viral Shedding

In 1971, Chang and Golden^{95,96} first described a “leukocyte transforming agent” in throat washings from four adults with IM. Although EBV was suspected, specific laboratory tests could not confirm it at that time.²²⁴ Other investigators, using more specific identification methods, soon identified EBV as the leukocyte transforming agent.^{211,407,439,459} Subsequent studies, utilizing virologic and DNA methods, suggested that most patients began shedding EBV in saliva during the acute phase of IM, and then shed virus either intermittently or continuously, with up to 20% of subjects shedding EBV at any one period of time. However, recent studies using much more sensitive polymerase chain reaction (PCR) methods have altered our view regarding EBV shedding.^{39,151,248,466} It is now clear that EBV can be detected in the mouth well before IM symptoms occur: EBV first appears at very low levels in saliva 4 to 5 weeks prior to symptoms; later, levels increase dramatically, at approximately 1 week before symptoms.¹⁵¹ Following the acute illness, virus continues to be shed from saliva in more than 95% of subjects. Hadinoto et al.²⁴⁸ have noted little change in concentrations of virus over short periods of time, but over months to years, large changes up to 4 to 5 log₁₀ can occur. This suggests variability in the infectiousness of EBV-positive patients, depending how much virus is being shed at that time.⁴⁶⁶

After IM, EBV DNA may be found in other biologic fluids or body sites, including the uterine cervix,^{576,621} the male reproductive tract,^{310,621} breast milk,³³⁵ and urine.³⁷⁶

TRANSMISSION

Common Modes of Transmission

Reports in the first half of the 20th century, before widespread acceptance and use of the heterophil antibody test, suggested the occurrence of epidemics of IM.^{251,462,625} However, researchers generally thought that the criteria used in most of those reports to establish the diagnosis of IM were inadequate to establish that the outbreaks were indeed associated with EBV.²⁸⁴ Although some success was reported for transmission of human EBV infections to certain primate species,³²⁹ attempts to experimentally infect humans with EBV collected from the oropharyngeal secretions, blood, urine, and feces of patients with IM generally failed.^{167,168,460,583} These experiments, conducted before development of specific EBV antibody tests, presumably were unsuccessful because most experimental subjects were immune as a result of having had a previous EBV infection.

Intimate sharing of oral secretions, typically through kissing, is the major source of EBV transmission in healthy populations.^{39,171,284} The fact that EBV infection is extremely common worldwide, especially in underdeveloped regions, suggests that the virus is spread relatively efficiently in the general population. Surprisingly, outbreaks of EBV infection are uncommon events. However, transmission of EBV, even among close contacts of a person with acute EBV infection, may occur slowly. Studies of families of index cases of IM have indicated that EBV is not transmitted efficiently,^{91,190,266} and one report⁹¹ describes a lack of EBV transmission from a man with IM to his EBV-seronegative wife after 16 months of follow-up. In addition, data from another family study indicated that after the index IM episode, EBV antibodies (seroconversion) developed in only 35% of the nonimmune sibling contacts after an average observation period of 5.6 contact months.⁶⁰⁰ Nonetheless, this same study also noted that the eventual seroconversion event in siblings was more likely to be associated with an IM episode than would be expected in the general population.⁶⁰⁰ The complexity of EBV transmission and induction of IM is suggested further by the finding of multiple strains and variability of strains in distinct body compartments of individuals with primary EBV infections.⁵⁷³

Evidence has shown that EBV replicates in oropharyngeal epithelial cells⁵⁷⁷; subsequent infection of B cells possibly occurs as a result of contact with these epithelial cells.⁶ However, it remains unclear which cells (B cells vs. oral epithelial cells) initially become infected following natural exposure to EBV via the oropharynx. Several models have been brought forward, but the answer remains elusive. Perhaps clues can be gleaned from a recent study involving college students incubating IM. Students had mouthwashes collected early in the course, which were negative for EBV DNA, pointing against lytic epithelial cell infection, and supporting possible early B-cell infection.¹⁵¹ Perhaps this or other similar clinical studies may soon reveal the answer to this mystery.

The incubation period for typical EBV-associated IM (32–49 days) has long been based on the seminal study of IM by Hoagland.²⁸⁴ In a case report, a teenager kissed his girlfriend just before her diagnosis of IM and began having symptoms 38 days later.⁶⁰⁴ Most recently, a modal incubation period of 42 days was calculated among college students followed prospectively who developed IM.³⁹

Transmission via Blood Products or Transplanted Organs

Transmission of EBV via blood transfusion has been reported.^{212,274,284,615,678} Also, a recent retrospective study suggests that EBV is associated with posttransplant transfusions in stem cell transplants.⁶³² Transmission of EBV via transfusion occurs much less commonly than with CMV, however. High levels of immunity, transfer of neutralizing antibodies during transfusion, and limited survival of B cells may account for the rarity of this occurrence.²⁷⁰ Despite WBCs potentially containing very high concentrations of EBV DNA,⁶⁴⁶ only one case of EBV infection due to leukocyte transfusion has been reported, in an immunocompromised adult.²¹⁴ In transplant recipients, EBV-positive donor organs may transmit EBV to the recipient.^{86,96,262}

Intrauterine and Perinatal Transmission

Because most females reaching child-bearing age already have been infected with EBV, primary infections during pregnancy occur infrequently.^{187,302,381} (see the later discussion of congenital infection).

EBV has been found commonly in breast milk from various populations. Several series report healthy women carrying EBV in breast milk at rates of 33% to 46%^{218,335}; HIV-infected mothers from South Africa had similar rates (27%).⁶⁴³ In another study from Africa, Daud et al.¹³³ prospectively measured the rate of EBV positivity and EBV concentration in breast milk from 94 mothers every 4 weeks (6, 10, 14, and 18 weeks) after delivery and noted a significant decrease over time.¹³³ Despite the presence of EBV in breast milk at substantial rates, and its potential transmissibility,¹³³ there is no evidence that this biologic material plays a major role in transmission of EBV to infants.³⁶⁸

Sexual Transmission

Detection of EBV in genital ulcers,^{253,510} the uterine cervix,^{52,576} and the male reproductive tract^{216,621} raises the possibility of venereal transmission. The first seroepidemiologic study examining EBV as a sexually transmitted agent was conducted by Higgins et al.²⁷⁸ in 2007 among a group of 2000 college students and indicated possible sexual transmission. However, the low concentrations of EBV in male and female reproductive tracts, compared to levels up to 10⁶ copies per mL in saliva,³⁹ support epidemiologic studies demonstrating saliva as the major vehicle for EBV transmission.³⁹

NONMALIGNANT CLINICAL SYNDROMES ASSOCIATED WITH EBV INFECTION

Primary EBV infection in children typically is silent but may result in mild clinical symptoms. Nonspecific clinical symptoms may include prolonged low-grade fever with or without lymphadenopathy, cough, rhinorrhea, fatigue and pharyngitis.⁶²⁸

Infectious Mononucleosis

EBV is the most frequent etiologic agent of IM. The signs and symptoms of classic IM^{39,93,153,158,185,285,596,598} develop in most adolescents and adults, as well as in some young children, when they experience a primary (initial) EBV infection. Factors determining an asymptomatic versus symptomatic response to EBV infection are largely unknown. The degree of viremia appears to be related to disease severity in some studies,^{38,39} but not in others.⁵⁶⁹

The incubation period is followed by a short mild prodrome of 3 to 5 days and may consist of malaise, fatigue, mild headache and possibly fever. At this stage, differentiation of IM from other viral infections is difficult.

Acute Phase

The prodrome is followed by the classic clinical features of IM (i.e., fever, sore throat, malaise, and fatigue), and physical examination reveals lymphadenopathy and tonsillopharyngitis (Table 160.1). The temperature ranges from 38°C (100.4°F) to 40.5°C (104.9°F) (usually <39°C [102.2°F]); the fever usually begins abruptly, is more prominent in the afternoon and evening, and persists for 1 to 2 weeks. On occasion, the fever may

last 4 to 5 weeks. Lymphadenopathy occurs in more than 90% of children and adults and typically involves the anterior and posterior cervical lymph nodes. Generalized lymphadenopathy can also be seen and involves the supraclavicular, axillary, epitrochlear, and inguinal chains. The presence of occipital, inguinal, or axillary lymphadenopathy has a higher specificity for the diagnosis of IM when compared to anterior cervical lymphadenopathy alone.¹⁵⁸ Affected nodes are slightly tender, non-erythematous, and moderately enlarged in a symmetric manner. Lymphadenopathy is most prominent during weeks 2 to 4 of the illness. The absence of lymphadenopathy reduces the likelihood of IM the most when compared to other findings.¹⁵⁸ Tonsillopharyngitis develops during the first week of illness and usually resolves abruptly the next week. The presence of palatine petechiae in adolescents and adults with sore throat strongly suggests IM.¹⁵⁸

Exudative pharyngitis, similar to that found with *Streptococcus pyogenes* pharyngitis, occurs in approximately half of patients (Fig. 160.1). *S. pyogenes* is present in the posterior pharyngeal region of 5% of patients with IM and probably represents carriage rather than simultaneous bacterial tonsillopharyngitis. Individuals with EBV infection shed higher numbers of viral particles if they are colonized with *S. pyogenes*.⁶³⁶

Splenomegaly occurs in approximately 50% of patients with IM but more frequently in younger children. Usually only the tip of the spleen

TABLE 160.1 Clinical Manifestations of Infectious Mononucleosis in Children and Adults			
Sign or Symptom	FREQUENCY (%)		
	Age <4 y	Age 4–16 y	Adults (Range)
Lymphadenopathy	94	95	93–100
Fever	92	100	63–100
Sore throat or tonsillopharyngitis	67	75	70–91
Exudative tonsillopharyngitis	45	59	40–74
Splenomegaly	82	53	32–51
Hepatomegaly	63	30	6–24
Cough or rhinitis	51	15	5–31
Rash	34	17	0–15
Abdominal pain or discomfort	17	0	2–14
Eyelid edema	14	14	5–34

Data from references 93, 185, 285, 596, 598.

is palpable, with maximal size developing by the end of the second week and typically resolving by the third or fourth week of illness. Massive enlargement of the spleen is very uncommon. Hepatomegaly occurs in approximately 60% of young children with IM and less commonly in older age groups. However, silent inflammation of the liver is a common finding.²⁹¹ Cough and rhinitis are noted frequently in children younger than 4 years old with IM, perhaps as a result of other concurrent viral infections. Rash (unassociated with antibiotic administration) develops in less than 15% of adults with IM but occurs more commonly in children and adolescents (18–34%)⁵⁹⁸ (Fig. 160.2). The strong correlation in young adults between the administration of ampicillin and the subsequent development of a rash (Fig. 160.3) is not observed in children with IM, possibly overshadowed by the overall increased incidence of cutaneous manifestations in children with IM (see [Complications of Infectious Mononucleosis](#) for a detailed discussion of rashes associated with IM). Children are more likely than are adults to have abdominal pain, failure to thrive, otitis media, and recurrent tonsillopharyngitis preceding or following IM.⁵⁹⁸ Eyelid edema is described in up to a third of adults but occurs less commonly (15%) in children.⁵⁹⁸

Resolution Phase

The acute phase of IM lasts several days to 3 to 4 weeks, with gradual and uneventful resolution in immunocompetent individuals. On occasion,

FIG. 160.2 Generalized exanthem on a 10-year-old boy with infectious mononucleosis. (Courtesy Dr. Luis A. Castagnini, Baylor College of Medicine, Children's Hospital of San Antonio, San Antonio, TX.)

FIG. 160.3 Ampicillin rash occurring in an adolescent with infectious mononucleosis after the administration of amoxicillin. (Courtesy Dr. James Brien, Scott and White Hospital, Temple, TX.)

biphasic illness is observed, with recrudescence of acute symptoms after significant improvement. Organomegaly may persist for 1 to 3 months. The severe fatigue usually resolves within 3 to 4 weeks, but several months may be required for persons with IM to fully resume their pre-illness activity levels.⁵²² There is evidence, albeit minimal, suggesting that subsequent fatigue-like syndromes in patients with IM may be related to (or predicted by) the presence of preexisting lower physical fitness or prolonged bed rest during convalescence, whereas mood disorders are more related to premorbid psychiatric history.⁶⁶²

Infectious Mononucleosis in Young Children

Increasing incidence of EBV-IM or IM-like illness is being reported in very young children, usually accompanied by compatible EBV-specific laboratory testing.^{103,146,206,598,599,651} Young children may have less intense EBV-specific serologic responses or not yield these immune responses until later in the disease course. EBV genomic testing by quantitative PCR of peripheral blood mononuclear cells and plasma has been suggested as a laboratory diagnostic aid in some cases.¹⁰³

Disseminated EBV Infection in X-Linked Lymphoproliferative Disease

Overwhelming primary EBV infection, seen rarely in immunocompetent patients, occurs more commonly in children with certain primary immunodeficiency disorders, most notably boys with X-linked lymphoproliferative disease (XLP).^{517,594} EBV infection triggers an excessive proliferation of EBV-infected B cells, macrophages, and cytotoxic T cells. Infiltration of tissues by a dysregulated immune system in conjunction with cytokine release causes parenchymal damage of the liver, bone marrow, kidneys, brain, and heart. These patients typically first present with features consistent with IM, including prominent lymphadenopathy and hepatomegaly, but fulminant disease (FIM) leading to death subsequently develops. Thrombocytopenia, anemia, and liver dysfunction are commonly seen early in the course of illness, followed by severe hepatitis, liver necrosis, acute hemorrhage, meningoencephalitis, and liver failure. Mortality rates from FIM exceed 75% in patients with XLP. Survivors usually have hypogammaglobulinemia, aplastic anemia, and B-cell lymphomas later in life.^{207,449,624} Widespread, uncontrolled lymphoproliferation and hemophagocytosis are usually found at autopsy. XLP is associated with the deletion or mutation of a specific gene (SLAM-associated protein) located in the chromosomal Xq25 region, which is involved in key cellular signaling pathways for immune responses^{116,457,557}; absence of this functional protein permits overwhelming and usually fatal infection from a primary EBV infection.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic syndrome, first described in 1939, is a rare but life-threatening condition characterized by excessive activation of the immune system. Hemophagocytosis (engulfment of erythrocytes, leukocytes, platelets, and their precursors) by activated macrophages is usually seen in bone marrow aspirates as well as in biopsies from liver, lymph nodes, or spleen⁵⁴³ (Fig. 160.4). Hemophagocytic lymphohistiocytosis (HLH) is characterized primarily by fever, pancytopenia, hepatosplenomegaly, and hemophagocytosis in lymphoreticular tissue. Since the initial description of its association with viral infections in 1979,⁵³³ numerous viral infections, including EBV, have been linked with HLH.^{209,477,525} Hereditary (familial) forms of HLH exist, most prominently those occurring in children with XLP (see preceding section).⁴⁴⁹ Male patients with EBV-induced HLH should be screened for XLP.²⁰⁹ A disseminated form of EBV infection with features of HLH may develop in these patients; most other cases are sporadic. In contrast to IM, which involves infection of B cells, primary infection in patients with sporadic HLH results in an EBV-driven T-cell proliferation with proinflammatory cytokines playing a central pathogenetic role.³¹⁴ Untreated EBV-associated HLH carries a high mortality rate.

Chronic Active Disease

Horwitz et al. first described patients with persistent or intermittent fever and lymphadenopathy and unusually elevated IgG against viral capsid antigen of EBV in 1975.²⁹² A similar clinical entity was described

FIG. 160.4 Bone marrow from an 18-year-old woman with Epstein-Barr virus–associated hemophagocytic lymphohistiocytosis revealing a macrophage (center) filled with phagocytosed red blood cells. (From *Blood* 93:1991, 1999. Photo courtesy Dr. Lindsey Baden and Dr. Frank Evangelista, Beth Israel Deaconess Medical Center, Boston, MA.)

by Virelizier et al. in 1978 in a 5-year-old girl with a severe disease characterized by persistent fever, lymph node enlargement, pneumonitis, hepatosplenomegaly, and thrombocytopenia associated with extremely high levels of IgG and IgM against EBV VCA and EA.⁶⁴⁴ In 1984, DuBois et al. proposed the term “chronic mononucleosis syndrome” to describe this entity,¹⁴⁹ and later the condition was called chronic, symptomatic EBV infection.⁵²⁹ Although these reports were published decades ago, chronic active Epstein-Barr virus (CAEBV) infection is not as well characterized as are other EBV-associated diseases.²⁰¹ It shares with HLH the central theme of infection and proliferation of non-B cells. CAEBV infection occurs more commonly in Asians,³⁵⁹ with children affected more frequently than adults. Two forms of the disease have been described, one involving EBV-infected T cells and the other affecting NK cells.^{356,357} Patients with the more severe form can be considered to have a chronic version of HLH, with similar symptoms and a uniformly poor prognosis. After having a typical IM-like illness, these patients develop persistent infection of their peripheral T cells (CD4⁺, CD8⁺, or both) and do not recover fully. Guidelines for the diagnosis of CAEBV have been proposed⁴⁷¹ and include (1) persistent or recurrent IM-like symptoms, (2) elevated EBV anti-VCA antibodies and anti-EA, and/or detection of increased EBV genomes in affected tissues, including peripheral blood, and (3) chronic illness that cannot be explained by other known disease processes at diagnosis. Patients with suspected CAEBV must fulfill each category. Continuous or intermittent signs and symptoms, persisting for 3 months or longer, typically include fever, hepatosplenomegaly, lymphadenopathy, headache, malaise, and fatigue.^{566,664,665} More severe cases display neurologic disease (e.g., encephalitis), malignant disease (e.g., lymphoma or leukemia), hepatic failure, hematologic disease (e.g., hemophagocytosis), cardiovascular disease (e.g., coronary aneurysms, valvular disease, or myocarditis) and disease localized to other organs (e.g., skin eruptions or pneumonitis).^{308,359} One distinctive characteristic of these patients is extremely high antibody titers against EBV replicative antigens, including VCA and EA, and low or absent responses to EBNA. Poor prognostic factors include older age and high EBV viral loads.³⁵⁹ Some cases may be related to mutations in the perforin gene.^{330,341} Clonal expansion of EBV-infected T cells probably plays a central role in disease pathogenesis.³⁵⁹ A second form of the disease, described principally in Japanese patients, is characterized by milder IM symptoms, less extreme EBV serologic abnormalities, granular lymphocytosis, and high IgE levels.³⁵⁶ Interestingly, these patients also typically develop pronounced skin reactions in response to mosquito bites.^{108,309} Large expansions of EBV-infected, CD56-positive NK cells are observed in peripheral blood and in the skin reactions. CAEBV infection should not be confused with chronic fatigue disorder, which has no clear association with EBV.

Congenital Infection

Primary EBV infection during pregnancy is rare, mainly because immunity to EBV exceeds 95% in women of child-bearing age.³⁸¹ The role of EBV as a potential cause of fetal infection is uncertain, and evidence of a link between infection and congenital anomalies is lacking. Chang and colleagues^{94,97} found only one EBV-infected specimen among 2696 samples of cord blood lymphocytes. However, in a study of more than 700 pregnant women, the persistence of EBV EA was associated with increased risk of adverse pregnancy outcomes, including fetuses with malformations, early fetal death, and prematurity.³⁰² More recently, investigators have demonstrated rare instances of in utero transmission of EBV confirmed by PCR,⁴³⁶ but adverse fetal outcomes have not been clearly documented. The strongest evidence of congenital EBV infection comes from case reports of infants with congenital anomalies attributed to EBV infection. Goldberg et al.²²³ reported a newborn infant who had bilateral central cataracts, cryptorchidism, hypotonia, and petechial rash. Laboratory evaluation showed thrombocytopenia, and EBNA was detected in the infant’s lymphocytes. In 1978 Brown and Stenchever⁷¹ reported an infant born to a mother with confirmed EBV infection; the infant died soon after birth with multiple malformations and a positive antibody titer to EBV on cerebrospinal fluid (CSF). However, confirmation by virologic studies was not possible in either of these cases.

Other Diseases

EBV has been linked with various autoimmune disorders in children and adults, primarily on the basis of seroepidemiologic information. Early reports^{78,560} of an association between EBV infection and subsequent development of rheumatoid arthritis have not been substantiated by a recent meta-analysis.⁴² On the other hand, large systematic reviews suggest that infection with EBV predisposes to the development of multiple sclerosis⁸ and systemic lupus erythematosus.²⁶⁰

COMPLICATIONS OF INFECTIOUS MONONUCLEOSIS

Acute EBV infection in a healthy child or adolescent, regardless of whether it is associated with typical IM, rarely is complicated by serious illness.⁵⁹⁶ The most frequent complications, exanthems and mild hepatitis, more appropriately are considered part of the normal spectrum of disease.³⁶⁵ More serious complications involving major organs have been reported regularly since IM first was described as a distinct clinical entity, but they remain rare (for review, see elsewhere^{9,317,494,598}). Most complications, including the more severe ones, are transient.

In one prospective study,⁵⁹⁸ significant complications involving mainly the pulmonary, neurologic, and hematologic systems were noted in approximately 20% of children with IM. Thrombocytopenia with hemorrhagic manifestations, severe airway obstruction, and neurologic complications developed in children with IM more frequently than in adults; jaundice occurred less frequently.

Exanthems

Ampicillin Rash

Historically, patients with IM were treated frequently with antibiotics, primarily for suspected streptococcal pharyngitis or bacterial lymphadenitis. Soon after the release of ampicillin, reports linked the antibiotic with the occurrence of exanthems in patients with IM. Two large case series have indicated that administration of ampicillin (or amoxicillin) precipitates an exanthem in most (95% to 100%) adolescents and adults with EBV-associated IM,^{485,515} but it is less common in children.⁵⁹⁸ This phenomenon has become known as the ampicillin rash associated with IM. The rash usually develops 5 to 10 days after treatment is initiated and resolves within a few days of discontinuation. Characteristically, the cutaneous lesions are maculopapular and pruritic and involve the trunk, face, and extremities (see Fig. 160.3).⁴⁸⁵ A rash also may develop in patients with IM treated with other antibiotics, including azithromycin¹³⁰ and cefprozil,³² but such rashes do not represent hypersensitivity reactions.

Other Exanthems

An exanthem will develop in approximately 3% to 15% of persons with IM not treated with antibiotics.^{34,285,327,425,522,598} These rashes are

maculopapular but can be urticarial, scarlatiniform, or erythema multiforme-like (see Fig. 160.2). Rarely, the rash has been described as vesicular or purpuric.⁷ Erythema nodosum also has been noted.⁶¹ Although most commonly associated with hepatitis B, some cases of Gianotti-Crosti syndrome (papular acrodermatitis of childhood) also have been related to primary EBV infection.²⁸⁸

Cardiac

Mild electrocardiographic abnormalities (mostly nonspecific ST- and T-wave changes) have been observed in 6% to 16% of adults with IM.^{153,286} Abnormalities usually are noted during the second or third week of illness and disappear by the fourth week, but they may persist longer. A case of myocarditis heralding typical IM has been noted in a young adult.⁶⁴⁸ Mild, asymptomatic and self-limiting pericardial effusion has been reported in children during the acute phase of IM.⁴⁸² Serious cardiac complications occur extremely rarely.¹⁹⁷

Hematologic

Hemolytic Anemia

Hemolytic anemia occurs in 1% to 3% of patients with IM,^{152,414,598} and many cases have been reported in children with previously unrecognized hemoglobinopathies. The anemia typically develops during the second or third week of illness and resolves in 1 to 2 weeks. Corticosteroid therapy may hasten resolution.²⁰⁸

Aplastic Anemia

This anemia is a rare complication of IM, with only scattered case reports in the literature.^{43,380,638,656} Steroids have been beneficial,²³⁶ but bone marrow transplantation has been necessary in some cases.^{14,396} Fatalities have been recorded, usually in association with pancytopenia.^{3,638}

Thrombocytopenia

Mild thrombocytopenia occurs in 25% to 50% of patients with IM^{80,83} and probably is immune mediated, related to the presence of autoantibodies to platelet glycoproteins,⁶¹³ although splenic sequestration may contribute. Platelet counts usually return to normal levels 4 to 6 weeks after the onset of illness, only on rare occasions lasting 8 weeks or more.⁸⁰ Severe thrombocytopenia (platelet counts $<20 \times 10^3/\text{mm}^3$) occurs rarely, with fewer than 40 cases identified in one review.⁵⁰¹ Most cases presented with petechiae, purpura, or bruising, and 30% had epistaxis.⁵⁰¹ The authors noted a complication rate of 27% and a mortality rate of 5% associated with severe thrombocytopenia. Case reports have suggested beneficial effects of corticosteroids^{400,611} or intravenous immune globulin^{150,613} for severe, life-threatening thrombocytopenia. Platelet transfusions provide only temporary improvement; however, patients who receive transfusions are less likely to develop complications of severe thrombocytopenia.⁵⁰¹

Neutropenia

Mild to moderate neutropenia occurs frequently during IM.^{81,84} Neutrophil counts typically reach their lowest values during the third and fourth weeks of illness but may persist for another month or more. Although severe neutropenia (absolute neutrophil count <200) and agranulocytosis are rare events, with patients recovering uneventfully, death from overwhelming bacterial infection has been reported.^{258,455} Antibodies against anti-human neutrophil-specific antigens elicited during EBV-induced polyclonal antibody stimulation probably are the source.^{559,683}

Pancytopenia

Pancytopenia has been reported to develop in a small number of children and adults with IM.³⁷¹ Fatalities attributable to overwhelming bacterial infection have occurred.^{313,638}

Spleen

Detectable splenomegaly develops in up to 50% of patients with IM; one study demonstrated splenic enlargement by ultrasound examination in 100% of patients hospitalized with IM.¹⁴⁵ Patients with a palpable spleen are at risk for having spontaneous rupture. In the United States, splenic rupture occurs in 0.1% to 0.5% of all patients with IM^{26,175,419};

male patients are more commonly affected, and about 50% of ruptures occur spontaneously.⁴¹⁹ The rate of splenic rupture in children is unknown but probably is lower. The risk of splenic rupture is not related to the severity of IM.¹⁹² Rupture typically occurs during the first to third week of illness and is heralded by abdominal pain. Signs of hypovolemia occur frequently and include orthostasis, tachycardia, and syncope. Pain in the left shoulder (Kehr sign),⁴¹¹ caused by diaphragmatic irritation from blood, is observed in approximately 50% of patients with splenic rupture; right shoulder and subscapular pain may develop as well.⁵⁵⁴ Splenic infarction following IM occurs rarely, but its presentation mimics splenic rupture and should be considered in patients with left upper quadrant abdominal pain. A recent literature review shows 19 of such cases, 12 of which were in patients 21 years of age or younger.²⁷⁶ Splenic abscess has been described in a child with IM.¹¹¹

To reduce the risk of splenic rupture, physicians customarily caution patients against engaging in strenuous physical activity and contact sports during recovery from the acute illness and for the period of significant organomegaly.^{549,652} Recommendations for reduced activity vary between 3 weeks and 6 months. In one review, the lack of evidence-based information about the timing of return to activity for athletes is acknowledged, and physicians are discouraged from making decisions on the basis of a single parameter.⁶⁵² Instead, individualized decisions must be made. In general, if the patient is asymptomatic without a palpable liver or spleen, a gradual return to pre-IM levels of light activity probably is safe. Some authors recommend avoiding contact sports or any strenuous activity associated with increased abdominal pressure (i.e., weight lifting, rowing) for at least 3 weeks after illness onset,^{27,419} while others recommend waiting a minimum of 4 weeks before returning to competitive contact sports.^{145,196} Some studies have evaluated the role of imaging procedures (e.g., computed tomography or ultrasonography) to assess spleen size and document resolution of splenomegaly, and while some show benefit of serial ultrasonography,⁴⁶⁵ imaging is generally not cost effective or accurate in determining the timing for normal activity.⁴⁵ Ultrasonography may be considered for asymptomatic athletes desiring to return to play early and for those with ambivalent examination findings.^{45,518}

Most cases of splenic rupture require emergency splenectomy.¹⁷⁵ However, in an effort to maintain the patient's hematologic and immunologic competence, practical management of splenic rupture is evolving. At some institutions, selected patients with splenic rupture who meet certain requirements, including hemodynamic stability with low transfusion requirements and a normal level of consciousness, may be managed with medical therapy²⁶ or endovascular interventional methods^{67,241} instead of traditional splenectomy.

Gastrointestinal Tract

Liver

Mild to moderate, subclinical inflammation of the liver occurs in more than 90% of patients with IM.²⁹¹ Rarely, more serious cases of hepatic disease, including fulminant hepatic failure in children, have been described.^{140,200,264,365,409,416,423} Mellinger and colleagues published a case series of consecutive adults with acute liver failure and found that less than 1% of all cases were related to primary EBV infection; however, the case-fatality rate was high.⁴³⁴ Rare pediatric cases of EBV-induced acute liver failure treated with liver transplantation have been reported.^{182,434} Chronic hepatitis also has been documented.⁶¹⁴

Other

Other gastrointestinal diseases purportedly associated with IM include pancreatitis, gastritis, typhilitis, proctitis and cholecystitis.^{364,365,399,568,688}

Neurologic

Acute neurologic disorders^{120,428,570} develop in 1% to 5% of persons with IM.^{51,285,428,570} Neurologic complications usually occur at the height of the typical manifestations of IM, but they also may develop during the resolution phase. In addition, some reports document neurologic disease as a heralding event, before the development of typical IM, or even as the sole manifestation of EBV infection, especially in children.^{63,141,144,165,448} The most common neurologic complications include those occurring in the CNS, such as aseptic meningitis, meningoencephalitis, and

encephalitis; however, other central and peripheral neurologic complications have been described.⁴²⁸ The pathophysiologic process of CNS manifestations is not well established. Possible mechanisms include direct viral invasion, immunologic mechanisms, and inflammation.³⁵⁵

Encephalitis and Aseptic Meningitis

EBV frequently affects the CNS, causing abnormalities in both CSF and electroencephalography, yet most patients exhibit no symptoms.⁴⁹² In two large series of patients with encephalitis, EBV was responsible for up to 10% of cases,^{143,347} and EBV caused 8% of cases of focal encephalitis.⁶⁶³ Clinical findings in EBV encephalitis include fever, headache, vomiting, seizures, alteration in mental status, focal deficits (i.e., bilateral leg weakness, leg spasticity, face and arm weakness, asymmetric reflexes) irritability, disorientation, lethargy, and, occasionally, a comatose state.^{141,143} Symptoms suggestive of schizophrenia, such as delusions, hallucinations, and extreme agitation, are seen occasionally. Patients with aseptic meningitis typically complain of a stiff neck, headache, fever, and vomiting. Symptoms of IM occur uncommonly in children developing EBV encephalitis. Typical CSF findings in children with EBV encephalitis include mild to moderate pleocytosis (lymphocytic predominance) in 50%, mildly elevated protein levels in half of cases, and normal glucose concentration.¹⁴⁴ EBV antibodies, EBV DNA, and even EBV virions have been identified in the CSF or brain tissue of persons with EBV-associated neurologic complications.^{2,143,255,303,328,355,490} Some reports suggest that the immune dysregulation caused by primary EBV infection may act as a triggering mechanism for the development of measles-associated subacute sclerosing panencephalitis.^{181,287} Because typical IM symptoms seldom occur in children with EBV encephalitis and clinical findings are not specific, EBV should be considered a possible etiology for any child with acute encephalitis. Fulminant and fatal outcomes have rarely been reported in children with EBV-associated meningoencephalitis.^{426,428}

Other CNS Manifestations

EBV-associated cerebellitis is a rare occurrence that develops primarily in children and young adults.^{109,114,120,165,220} Full recovery occurs within weeks to months. Cranial nerve palsies, singly or in combination, also occur rarely; the facial nerve is affected most commonly, including bilateral involvement in some cases.^{435,619} Other manifestations of cranial nerve involvement include optic neuritis,^{143,194} dysarthria from hypoglossal nerve palsy,⁶⁸⁷ deafness,^{165,666} and ophthalmoplegia.⁵⁵¹ Some cases of brain stem encephalitis,^{463,565} radiculomyelitis, and recurrent aseptic (Mollaret) meningitis²²⁷ have been reported.

Non-CNS Neurologic Complications

Guillain-Barré syndrome (ascending polyradiculoneuritis) is the most common neurologic complication of EBV infection outside the CNS.^{237,238,528} Others include peripheral neuropathy,¹⁵⁵ autonomic dysfunction,⁶⁷⁶ hemiplegia,³⁶ and transverse myelitis.^{143,633}

Renal

Silent abnormalities of the urine sediment, including proteinuria and microscopic hematuria, occur commonly in patients with IM.^{285,387} However, clinically significant renal disease is an extremely rare event. Tubulointerstitial nephritis, acute tubular necrosis, and nephrotic syndrome have been observed most commonly.^{60,438,641} Acute renal failure with and without rhabdomyolysis has been reported.^{195,390,464,475,641} Some children and adolescents have developed hemolytic-uremic syndrome related to acute EBV infection.^{385,564,571}

Respiratory Tract

Airway Obstruction

Severe airway obstruction is one of the most common indications for hospitalization in children with IM.³¹⁷ Alpert and Fleisher⁹ observed severe airway obstruction in a fourth of children admitted for complications of IM. Overall, it is estimated that up to 5% of children and adults will develop this complication over the course of their illness.³¹⁷ Patients typically have severe tonsillopharyngitis with progressive symptoms of airway obstruction, usually in association with dysphagia and odynophagia. Airway obstruction may occur at any of several levels, including

inflammation and hypertrophy in the Waldeyer ring, edema of the epiglottis and pharynx, and development of pseudomembranes in large airways.^{219,246} Acute onset of obstructive sleep apnea in children with IM has rarely been reported.¹⁰² Management of airway obstruction has included systemic corticosteroids, tonsillectomy, tracheostomy, and nasopharyngeal airway placement, as well as general supportive measures such as humidification and elevation of the head of the bed.^{582,669} Nonsurgical management, including the systemic administration of steroids, usually is beneficial, although tonsillectomy may be necessary in refractory cases.^{582,591,669} With the widespread availability of intensive care and mechanical ventilation, mortality from this complication is much lower than previously observed.

Neck Abscesses

Cervical and peritonsillar abscesses have been described in association with IM.^{76,259,326,660} This uncommon complication follows severe tonsillopharyngitis in patients with IM and typically is caused by bacteria found in the oral cavity, including alpha-hemolytic streptococci and anaerobes. Appropriate management includes administration of antibiotics and surgical drainage. Some concern exists that corticosteroid therapy of incipient airway obstruction may predispose to the development of an abscess.^{76,259} Gold and colleagues reported the case of a 17-year-old girl with IM treated with corticosteroids for the management of airway obstruction who subsequently developed jugular vein suppurative thrombophlebitis (Lemierre syndrome).²²¹ On the other hand, abscesses may develop in the absence of previous corticosteroid therapy.^{205,509}

Pulmonary Disease

Radiographic evidence of pulmonary infiltrates occurs in 0% to 5% of patients with IM,^{153,377} yet significant symptoms rarely are present.^{153,285,377} Some cases of IM with pulmonary manifestations may represent coinfection with other etiologic agents.^{20,184} However, several immunocompetent adults (but few children) with acute EBV infection have been described with pulmonary disease seemingly unrelated to other organisms.^{115,254,432,467} Typically, unilateral or bilateral interstitial infiltrates are observed, and pleural effusions may be present.^{100,156,363} In some cases, EBV has been detected in lung tissues.^{588,639} Recovery is the rule, although mechanical ventilation may be necessary.

Psychiatric

Chronic Fatigue

In the early 1980s, a chronic debilitating disorder, now designated chronic fatigue syndrome or systemic exertion intolerance disease (SEID/CFS),²⁰⁴ began receiving increased publicity and purportedly was linked etiologically to EBV.^{331,593} The syndrome occurs more commonly in middle-aged women and is characterized primarily by at least 6 months of debilitating fatigue leading to a substantial reduction in level of activity. Accompanying symptoms may include low-grade fever, mild lymphadenopathy, pharyngitis, neuropsychological problems, sleep disturbances, headache, and other symptoms.⁵⁹² The association with EBV was drawn mainly from epidemiologic features and some abnormal EBV-specific immune responses. Variable general immunologic abnormalities have been described in some cases. However, no consistency exists in these findings, and a plausible pathogenetic association has not been demonstrated. Most experts today do not regard EBV as an etiologic agent in the development of this syndrome, although it may play a contributory role along with other infectious etiologies (e.g., human herpesvirus 6, CMV, Lyme disease, giardiasis).³⁴⁴ Performing diagnostic tests for infections, including EBV, is not routinely recommended for patients with SEID/CFS. Variably prolonged episodes of fatigue symptoms after IM continue to be reported, particularly among young adult women and those with premorbid mood disorders.^{345,496}

"Alice in Wonderland" Syndrome

This unusual syndrome, technically termed metamorphopsia, is a visual illusion manifested as a distortion in size, form, movement, or color, and it is associated most commonly with migraine headaches, epilepsy, and hallucinogenic drugs. Infections have also been associated with the development of this syndrome.^{58,453} Copperman¹²¹ first described its association with IM in 1977, and other similar cases also have been

described.^{112,166,373,374} Onset may occur during or soon after resolution of the clinical IM symptoms, and it may resolve within 4 to 6 weeks. Visual evoked potentials suggest diminished cerebral perfusion in affected patients.³⁷³

Miscellaneous Complications

Other complications purportedly associated with IM or primary EBV infection include recurrent tonsillitis,⁶⁴⁰ sinusitis,⁶⁰² periorbital cellulitis,⁶⁰² ocular disease,⁴²⁷ acute dacryocystitis,²¹⁵ rhabdomyolysis,⁴⁷⁴ genital ulcers,^{4,256,510,553} proctitis,³⁶⁵ and orchitis.⁵²¹ EBV has been implicated in the pathogenesis of advanced types of periodontal disease.⁵⁷⁸

MALIGNANT DISEASES ASSOCIATED WITH EPSTEIN-BARR VIRUS

Burkitt Lymphoma

Endemic BL is a rapidly progressive and fatal tumor that predominantly affects young children in central Africa and Papua New Guinea (Fig. 160.5).⁷⁵ Approximately 60% of African patients with BL present with jaw masses; abdominal masses are second most common.⁶⁸⁹ Jaw involvement occurs more commonly in younger patients (peak incidence at 3–7 years).⁴⁴¹ Less common sites include the CNS and the eye, with bone marrow involvement being rare. In patients with sporadic BL, the abdomen is the most common site involved at presentation (60–80%), with head and neck second most common (e.g., lymph glands, oropharynx and nasopharynx, sinuses).⁴⁴¹ Bone marrow is involved in 20% of patients. In some patients with BL and some with congenital or acquired immunodeficiencies (including AIDS), CNS involvement is present or eventually develops and is characterized by intracranial mass lesions of lymphomatous cells or a CSF pleocytosis consisting of malignant cells, or both.^{18,689,691}

Hodgkin Lymphoma⁵¹⁶

Pediatric HL is divided into two categories: childhood HL (age <14 years), and “AYA” (adolescent/young adult, 14–35 years). HL rarely occurs in children younger than 5 years in Western countries, but it is seen more commonly at younger ages in developing countries. Painless cervical or supraclavicular lymphadenopathy is the most common presentation for both age groups, with obstructive symptoms secondary to mediastinal lymphadenopathy occasionally seen. Constitutional symptoms such as fever, night sweats, and weight loss develop in approximately one fourth of patients with HL, and these symptoms worsen the prognosis. Of the four HL histologic subtypes, AYA patients display one predominant histology—nodular sclerosis (65–80%), whereas 90% of patients with childhood HL have nodular sclerosis or mixed cellularity.

Nasopharyngeal Carcinoma

NPC occurs primarily among adults in east and southeast Asia, accounting for 0.6% of cancers worldwide; the tumor is extremely rare in Western countries.¹¹⁰ In endemic regions, children younger than 16 years account for only 1% to 2% of all cases of NPC, but this age group accounts for 10% of NPC cases in the United States.^{110,305,397} Within the nasopharynx, the fossa of Rosenmüller is typically the tumor’s epicenter; from there

it invades adjacent organs and anatomic spaces. Symptoms at presentation in children include a painless unilateral neck mass, nasal symptoms (congestion, epistaxis, discharge), auditory symptoms (otalgia, otitis media, hearing loss, tinnitus), headaches, and cranial nerve abnormalities (cranial nerves III, V, VI, and XII most likely).^{29,110} Metastasis to cervical lymph nodes occurs in 75% of patients.

Posttransplant Lymphoproliferative Disease

Children immunosuppressed for organ transplantation have an increased risk for development of EBV-related lymphoproliferative syndromes and B-cell lymphomas (collectively termed PTLD).^{281,367,584} Ho and colleagues²⁸¹ reported a greater frequency of lymphoproliferative lesions in pediatric transplant recipients (4%) than in adult transplant recipients (0.8%). Pediatric organ transplant recipients are thought to have an increased risk for development of EBV-related PTLDs because, compared with adult transplant recipients, they are more likely to be seronegative for EBV at transplantation, and primary infection is more likely to progress to PTLD and other severe EBV-associated disorders.^{281,282} Recipients acquire EBV via passenger WBCs in the allograft, blood transfusions, or more naturally via exposure to EBV-positive saliva.²³¹ Some variability exists in the incidence of PTLD according to the specific organ transplanted. The incidence is highest in children receiving intestinal transplants (11%),²²⁸ which is postulated to be attributable to stronger immunosuppressive regimens and greater loads of lymphatic tissue in the grafts. The incidences of PTLD are lower in other pediatric organ transplant populations. One year and 5 years after pediatric solid organ transplantation, the PTLD incidence was 1.3%/2.4% (kidney), 1.6%/5.7% (heart), 2.1%/5.4% (liver), and 4%/16% (heart and heart/lung).²³¹ After human stem cell transplantation, the 10-year cumulative incidence rate for PTLD is approximately 1% overall.¹²⁷

The clinical history, physical examination findings, and confirmatory virologic laboratory testing are required to establish a diagnosis of PTLD. Symptoms may be nonspecific, especially early in the course, and include fever, malaise, weight loss, abdominal symptoms (bleeding, nausea, vomiting), sore throat, swollen lymph nodes, headache, focal neurologic symptoms, and indications of graft dysfunction.²³¹ On examination, signs may include lymphadenopathy, large tonsils, hepatosplenomegaly, pallor, subcutaneous nodules, and focal neurologic findings.²³¹

Posttransplant EBV-positive smooth muscle tumors (PTSMTs) have been described in children and adults undergoing solid organ transplantation.³³² Interestingly, previous PTLD occurs in approximately 40% of pediatric cases, but in less than 5% of adults.

Lymphoproliferative Disease in Other Immunodeficient Patients

Patients with a wide variety of primary immunodeficiencies (e.g., Wiskott-Aldrich syndrome, ataxia-telangiectasia, Chédiak-Higashi syndrome) as well as iatrogenically immunosuppressed patients (e.g., patients receiving cancer chemotherapy) also are at risk for development of various EBV-associated lymphoproliferative diseases and severe atypical EBV infections.⁴⁷⁸ EBV-associated diseases reported in these patients include severe IM, HLH, lymphoproliferative disease, BL, HL, diffuse large B-cell lymphomas (DLCLs), smooth muscle tumors, and mesenchymal tumors.⁴⁷⁸ One should keep in mind, however, that most immunocompromised children with acute EBV infections display minimal symptoms, or have a clinically silent course, similar to immunocompetent persons.^{273,281}

Other Malignant Diseases

Gastric carcinomas are more common in Asia, but they are extremely rare in children. EBV is associated with approximately 10% of cases worldwide, but is found in the majority of tissues from patients with gastric tumors displaying an undifferentiated (lymphoepithelioma-like) histopathologic pattern.³⁵² Aberrant DNA methylation is important in the pathogenesis of EBV-associated cases, with viral proteins and micro RNAs also playing roles.⁶⁷⁹

Other rare lymphoproliferative diseases (B-cell and T-cell) as well as carcinomas have putative associations with EBV. The strengths of these associations is variable. These include pyothorax-associated lymphoma, lymphomatoid granulomatosis, plasmablastic lymphoma,

FIG. 160.5 African boy with Burkitt lymphoma involving the jaw. (Courtesy Dr. George Miller, Yale University.)

systemic EBV-positive T-cell lymphoma, angiohistiocytic T-cell lymphoma, enteropathy-associated T-cell lymphoma, extranodal T/NK-cell lymphoma (nasal type), and aggressive NK-cell leukemia.^{85,148,202,312,657,675}

Epstein-Barr Virus and Human Immunodeficiency Virus

Several studies have indicated that underlying HIV infection is responsible for abnormal responses to EBV infections. These findings probably are attributable to the relative ineffectiveness of T cells from patients with AIDS in controlling EBV-infected lymphocytes.⁵⁹ In HIV-infected adults, these unusual reactions include exaggerated antibody responses to certain EBV antigens, including VCA and EA,⁵²⁰ and enhanced oropharyngeal shedding of EBV.^{10,183,320} Oropharyngeal shedding of EBV occurs more commonly in younger HIV-infected children, and children whose HIV disease progressed more rapidly had a substantially higher rate of excretion.^{183,320} Infection with EBV develops in HIV-infected children more frequent and at an earlier age and is more likely to involve hepatosplenomegaly and pneumonia compared to HIV-uninfected infants.^{491,579} In addition, HIV-infected infants have higher EBV viral loads, are more likely to be coinfecting with both EBV genotypes, and are generally poor controllers of EBV viremia.^{498,579} Whether EBV contributes directly to the progression of immune deficiency in these patients continues to be a matter of conjecture, although in vitro studies do indicate that some EBV proteins (e.g., LMP, BZLF1) are able to transactivate HIV-1.^{257,420}

Certain lymphoproliferative and other diseases develop in HIV-infected patients at rates higher than those in healthy persons.^{54,124,472,567} The immune activation triggered by HIV infection is thought to be responsible for B-cell stimulation and EBV-infected cell expansion, which may favor the development of EBV-related lymphoproliferative diseases.⁴⁹⁷ In addition, several HIV proteins (e.g. gp120, Tat, and Nef) are able to induce polyclonal B-cell activation.⁵⁰⁰ EBV-associated lymphoproliferative diseases include NHL, HL, body cavity lymphoma, smooth muscle tumors, lymphocytic interstitial pneumonitis (LIP), and oral hairy leukoplakia (OHL).

Lymphomas

NHL has remained the most common malignant disease occurring in children with AIDS^{54,106} and is an AIDS-defining condition.⁸⁸ In the present era of combination antiretroviral therapy (cART), NHL also has surpassed Kaposi sarcoma as the most common malignant disease in adults.¹⁶⁰ In one pediatric study, approximately one third of NHL tumors contained EBV DNA.⁴³¹ Primary CNS lymphomas are extremely rare occurrences in healthy children, but they have accounted for 8%⁴³¹ to 23%⁵⁴ of NHLs in children with AIDS. Primary CNS lymphomas are linked strongly to EBV, with the virus present in virtually every case.⁴¹⁵ Pediatric patients with AIDS and NHL typically have systemic symptoms of fever and weight loss. Signs of extranodal disease include hepatosplenomegaly, abdominal distention, jaundice, bone marrow involvement, and, rarely, CNS symptoms.⁴³⁰ Although it is not an AIDS-defining condition, HL in adults with HIV infection historically has occurred at rates 5 to 15 times higher than in the general population. HL is an uncommon occurrence in HIV-infected children, but it has been described.^{11,431,512} HIV-infected patients, including children,⁵¹² appear more likely than non-HIV-infected patients to present with disseminated disease, sometimes without obvious nodal involvement on physical examination.⁵⁰⁵ In patients with HIV infection, including children, the incidence of HL has increased in the cART era.^{11,160} Interestingly, HL incidence rates are higher in patients with moderate compared with severe immune suppression, and the increased incidence is postulated possibly to be related to the inability of EBV-infected H-RS cells to recruit sufficient lymphocytes and histiocytes for their survival.⁵⁶

Body cavity lymphoma (or primary effusion lymphoma) is a rare malignant disease that occurs almost exclusively in adult patients with AIDS, but it has been reported in children.³⁸³ Patients typically have immunoblastic lymphomatous effusions without solid tumors in body cavities, such as the peritoneum or pleura.⁴⁵² More than 75% of these nonsolid tumors are associated with human herpesvirus 8; however, EBV also is identified frequently in tumor cells. EBV may play a cofactorial role in the pathogenesis of these unusual tumors.⁵²⁷

Smooth Muscle Tumor

Leiomyosarcoma is an extremely rare occurrence in healthy patients,⁶⁸² but it is the second most common malignant disease in children with AIDS^{429,681} and is an AIDS-defining condition (Category B).⁸⁸ It also has developed in solid-organ transplant recipients³⁸⁶ and in patients with other types of immunodeficiency.⁴³⁷ EBV may be responsible for the unusually high incidence of these smooth muscle tumors found in children with AIDS.^{319,431} Leiomyosarcoma tissues from patients with AIDS have high concentrations of EBV (CD21) receptors, contain clonal (or oligoclonal) EBV DNA, and express EBERs and EBNA-1.^{319,431} In addition, some tumors demonstrate overexpression of *myc*, a proto-oncogene that leads to cell proliferation.³²¹ Leiomyosarcoma may develop in any smooth muscle tissue in patients with AIDS, but more typically it is noted first in the gastrointestinal tract and lungs. Tumors can appear simultaneously in multiple locations in the same individual.¹³⁷

Lymphocytic Interstitial Pneumonitis

LIP is a lymphoproliferative disease that occurs primarily in children with AIDS.¹⁹ In the era before cART, the incidence of LIP was 12% to 17% among children^{225,561}; in the cART era, this incidence has dropped to less than one case of LIP per 1000 person-years. Previous serologic and virologic evidence pointed to an association with EBV,^{19,343,523,547} but the exact role that EBV plays in this lymphoid proliferation is unclear at present. Children with LIP typically present in the second or third year of life.⁵⁶¹ The presence of LIP is generally associated with an improved prognosis for survival.⁵⁴⁷ On radiographic examination, diffuse, bilateral reticulonodular and interstitial infiltrates are noted.⁵⁰³ Many infants are asymptomatic, and whereas some children remain stable for long periods, others may exhibit a slow but relentless progression to chronic lung disease typified by tachypnea, cough, wheezing, and hypoxemia. Generalized lymphadenopathy and chronic parotitis may accompany LIP.⁶⁰⁷ Advanced disease is characterized by clubbing, wasting, cor pulmonale, and bronchiectasis.

Oral Hairy Leukoplakia

OHL is a nonmalignant squamous cell proliferation that develops in the oropharynx of HIV-infected patients. Although a common occurrence in adults, it occurs in less than 5% of HIV-infected children.⁴¹⁷ EBV DNA and virus replication can be detected within epithelial cells,^{234,581,650} with defective variants possible.²⁰³ OHL lesions are manifested as painless nonremovable gray or white plaques on the lateral surface of the tongue; rarely lesions can develop elsewhere in the mouth. Typical lesions often have vertical corrugations and a shaggy or "hairy" appearance when dry. OHL does not have any malignant potential, and treatment is not routinely necessary.^{348,562}

DIAGNOSIS OF INFECTIOUS MONONUCLEOSIS

General Laboratory Findings

Patients with IM typically have an absolute lymphocytosis (defined as absolute count of >4500/ μ L or >50% lymphocytes), prominent atypical lymphocytes (usually >10% of total leukocytes), and a positive test result for Paul-Bunnell heterophile antibodies (positive differential heterophile).¹⁸⁸ The atypical lymphocytes observed in the blood of patients with mononucleosis (Fig. 160.6) predominantly consist of activated T lymphocytes responding to the B-cell infection.⁴⁸⁸ Although often considered a hallmark of IM, atypical lymphocytes also may be observed in association with CMV infection, toxoplasmosis, measles, mumps, roseola, rubella, drug reactions, and other conditions.^{107,673}

For a typical uncomplicated case of IM, establishing a specific diagnosis of EBV infection is unnecessary; a complete blood count, differential, and heterophile antibody test are sufficient for diagnostic testing.^{57,68,188} The results of these tests are uncommonly normal early in the course of disease, and thus the tests may need to be repeated during the first 2 to 3 weeks before diagnostic results are achieved. In adolescent and adult patients with classic IM symptoms, a positive heterophile antibody test has a sensitivity and specificity of approximately 85% and 100%, respectively.²²⁹ The false-negative rates of the heterophile antibody test can be as high as 25% during the first week of illness, 5%

to 10% in the second week, and 5% in the third week.¹⁵⁷ The specificity of lymphocytosis (>50% of the absolute lymphocyte count) and presence of atypical lymphocytes (>10% of total leukocyte count) is 85% and 92%, respectively.^{68,158} The clinician should be aware that very young (<4 years) patients with primary EBV infection frequently have a negative heterophile test result,⁵⁹⁹ and only 25% to 50% of children under 12 years of age have a positive test result.^{406,414} Some studies suggest that a higher ratio (>0.35) of lymphocytes to white blood cell counts⁶⁷⁰ or the detection of lymphatic tissue with fibrinous membranes observed by nasopharyngeal endoscopy⁶⁵⁴ may distinguish between IM and acute bacterial tonsillitis.

Heterophile antibodies classically were measured as sheep erythrocyte agglutinins.⁴⁸⁹ Beef, ox, and horse red blood cells also are agglutinated by the heterophile antibodies found in the serum of patients with IM, but these heterophile antibodies do not bind to guinea pig kidney antigen extracts. These properties of mononucleosis heterophile antibodies distinguish them from the naturally occurring Forssman heterophile antibodies and from the heterophile antibodies found in serum sickness and other conditions. Thus, traditional tests for Paul-Bunnell heterophile antibodies involve absorption of the test serum with beef or ox red blood cells (which remove Paul-Bunnell heterophile antibodies) and guinea pig extract (which does not remove them). Tests in current use (e.g., mono test, Mono-Diff, Monospot) typically use horse red blood cells, which provide a more sensitive assay than do sheep erythrocytes. However, when horse erythrocyte agglutination tests are performed, the specificity of a positive result always should be confirmed by absorption of the serum with at least guinea pig kidney extract or, preferably, with both guinea pig kidney extract and beef (or ox) red blood cells. Materials for the absorption steps are included in many but not all of

the kits available commercially. Another heterophile antibody test, the beef (or ox) erythrocyte hemolysin assay, does not require absorption of the test sera but is somewhat less sensitive than is horse erythrocyte agglutination testing. Other tests^{191,250,391,539} using purified forms of heterophile antigen do not seem to offer any significant advantage over the rapid slide test using horse erythrocyte agglutination.

Other laboratory tests in patients with severe mononucleosis syndromes or in those with atypical clinical manifestations may indicate involvement of major organs, but such involvement rarely is associated with severe complications (see the previous section, Complications of Infectious Mononucleosis). These laboratory abnormalities include elevated transaminase levels, mild hemolytic anemia, and neutropenia.

EBV-specific laboratory testing should be reserved for patients with an EBV-suspected disease (1) lacking a heterophile antibody response, (2) exhibiting atypical, severe manifestations, or (3) associated with significant lymphoproliferative, oncogenic, or chronic findings.⁵⁹⁷ In most cases of EBV-associated IM episodes in immunocompetent patients, EBV-specific serology (i.e., antibody determination) is sufficient to affirm the viral-specific diagnosis. Isolation of virus from body secretions, fluids, and tissues (see later section, Virus Isolation) is labor intensive and not widely available. Quantitation or semiquantitation of EBV-specific viral load provides some measure of activity or putative influence of the virus in a variety of EBV-associated diseases. Other laboratory methods demonstrating high concentrations of actively replicating virus or latent antigens (such as immunohistochemical methods for antigen testing or quantitative PCR) may be more useful in associating EBV infection with disease, particularly in immunocompromised patients (Table 160.2).

Epstein-Barr Virus Antibodies

The viral-specific diagnosis of EBV-associated primary infections as IM in immunocompetent individuals (and commonly in immunocompromised patients) usually requires three types of antibody analysis on acute serum: IgG to EB VCA (VCA IgG), IgM to EB VCA (VCA IgM), and IgG to EBNA (EBNA IgG).⁵⁹⁷ (The EBNA complex is composed of six nuclear antigens or proteins, principally EBNA-1; the antibody response to the complex will herein be referred to as IgG to EBNA, or EBNA IgG.) The three EBV antibodies can be detected by commercially available immunofluorescent techniques or by various enzyme immunoassays. The need to add the determination of IgG to EB early antigen, a serologic response commonly found early in the primary infection, usually is not necessary for IM-like episodes.

Evolution of the serologic response to EBV antigens after a prototypic EBV-associated IM episode is depicted in Fig. 160.7. By the time clinical evaluation for IM and probably other forms of primary EBV infection is performed, an appreciable antibody response to EBV VCA has developed in most persons.^{269,599} In the case of primary infections (e.g., IM), the initial serum sample often contains both IgG and IgM antibodies to VCA. Most children also have (or will develop shortly) antibodies

FIG. 160.6 Atypical lymphocytes in the peripheral blood of a patient with infectious mononucleosis. (Courtesy Dr. Margaret Gulley, University of North Carolina, Chapel Hill, NC.)

TABLE 160.2 Summary of Laboratory Tests for Epstein-Barr Virus (EBV)-Associated Diseases

Detection of	Test	Purpose
Antibodies	Heterophile antibody EBV antibodies	Detect heterophile antibodies indicating infectious mononucleosis (more reliable in patients >4 y) Measure antibody response to viral proteins in serum samples; distinguish acute from remote infection
EBV DNA and RNA	Southern blot In situ hybridization RNA (EBERs) DNA PCR	Assess clonality of lesions with respect to EBV DNA structure; distinguish latent from replicative infection Identify EBER transcripts in specific cell types within histologic lesions Identify EBV DNA in specific cell types within histologic lesions Detect and quantitate EBV DNA in blood or CSF to diagnose and monitor disease
EBV proteins	Immunohistochemistry	Identify EBV protein expression in specific cell types within histologic lesions; distinguish latent from replicative infection on the basis of expression profiles
EBV	Virus culture Electron microscopy	Detect infectious virions or latently infected B cells; impractical for routine clinical use Identify whole virions representing replicative infection; impractical for routine clinical use

CSF, Cerebrospinal fluid; EBER, EBV-encoded RNA; PCR, polymerase chain reaction.

Modified from Gulley ML. Molecular diagnosis of Epstein-Barr virus-related diseases. *J Mol Diagn*. 2001;3:1-10.

FIG. 160.7 Evolution of antibodies to various Epstein-Barr virus antigens in patients with infectious mononucleosis. The titers are geometric mean values expressed as reciprocals of the serum dilution. The minimal titer tested for viral capsid antigen (VCA) and early antigen (EA) antibodies was 1:10; for Epstein-Barr nuclear antigen (EBNA), it was 1:2.5. The immunoglobulin (Ig) M response to capsid antigen was divided because of the significant differences noted according to age. (From Jensen HB, Ench Y, Sumaya CV. Epstein-Barr virus. In: Rose NR, de Macario EC, Folds JD, et al, editors. *Manual of Clinical Laboratory Immunology*, 5th ed. Washington, DC: American Society for Microbiology; 1997:634-43.)

to the EA complex, which can be measured separately as antibodies to the restricted (R) or diffuse (D) components.^{189,599} During the early phase of primary infection, most persons do not have detectable IgG antibodies to EBNA; a few have marginally detectable anti-EBNA titers. Thus, the serologic diagnosis of a recent or current primary EBV infection typically consists of a positive IgG and IgM anti-VCA response and negative anti-EBNA, with positive results in the anti-EA assay, if it is performed.

After the acute primary EBV infection (reflected in IM), IgM antibodies to VCA typically disappear within 2 to 3 months, and IgG antibodies to EA usually disappear within 6 to 12 months after infection (see Fig. 160.7).^{597,599} IgG anti-VCA and anti-EBNA antibodies persist for life and are indicative of a typical, chronic virus-carrying state.⁵⁹⁹ Some studies also have shown the persistence of anti-EA antibodies for several years after an acute EBV infection and the occasional appearance of anti-EA antibodies in healthy seropositive persons; however, the clinical or virologic importance of this finding is not clear. Heterophile antibodies are detectable during the first or second week of illness and may persist for months and sometimes for a year or more in persons who have recovered from IM; they remain detectable longer (usually more than a year) when the more sensitive horse erythrocyte agglutination and a quantitative method to determine the antibody response are used.

The antibody profile for an acute primary EBV infection, particularly that associated with an IM episode, is relatively clear in comparison with the variability of serologic or antibody profiles found in persons with other EBV-related disorders (Table 160.3). When a disease is not a consequence of primary infection but may be related to persistent or reactivated EBV infection (e.g., BL, NPC, some lymphomas of immunocompromised hosts, some chronic or atypical illnesses), the following serologic profile may be observed: positive IgG anti-VCA, often in high titer; usually negative IgM anti-VCA; often elevated anti-EA titer; and positive anti-EBNA assay (although sometimes at low titer and occasionally undetectable).^{259,270,273,318,517,594} Of note is that males with XLP frequently have no or low levels of EBV antibodies in response to EBV infection.⁵⁵⁰

Some studies^{424,531,540} suggest that monitoring for decreases in anti-EBNA antibodies or identification of increased immunologic mediators such as interleukin-4 and soluble CD23 and increased circulating EBV may be useful in providing early serologic signs of EBV-associated tumor development in organ and bone marrow transplant recipients. Further, testing for IgA antibody responses to EBV antigens may be helpful in establishing a diagnosis of acute infection in immunocompetent individuals⁵³ and evaluating the response to therapy for NPC.³³⁷

Molecular cloning of subregions of the EBV genome into high-expression plasmid vectors can generate large amounts of pure proteins containing EBV-encoded polypeptide sequences for use in immunoblot and enzyme-linked immunosorbent assay (ELISA)-based tests.^{74,90,174,279,531,540} These methods have extended the availability and use of EBV laboratory diagnosis and follow-up. There are a growing number of commercially available EBV serologic tests, particularly enzyme immunoassays.^{72,277} Yet after several decades of use, immunofluorescent techniques still remain the gold standard in EBV-specific serologic testing because of their overall excellent specificity and sensitivity. However, they require more expensive equipment, time, effort, and experience in interpretation. ELISAs are important alternatives for serologic testing because of their ease of performance and enhanced sensitivity. However, their specificity may be inferior to that of immunofluorescent techniques.³⁹³ It is noteworthy that there is insufficient standardization of antigen preparation, antigen and substrate selection, and cross-comparability of serologic techniques and manufacturers involved with commercially available EBV serologic tests. Therefore, interpretations should be drawn carefully, particularly with serum of young children, an age group that has been less well evaluated.³⁹⁴

Improvements in standardization as well as in specificity and sensitivity of commercially available serologic testing would benefit the laboratory diagnosis of primary EBV infections. Current EBV-specific serologic testing for nonprimary infections, particularly in immunocompromised patients, provides more limited diagnostic interpretations. The expanding capacity in the detection and quantitation of EBV viral load in body

TABLE 160.3 Correlation of Clinical Status and Characteristic Serologic Responses to Epstein-Barr Virus (EBV) Infection^a

Clinical Status	Heterophile Antibodies (Quantitative Test)	RESPONSE TO EBV-SPECIFIC ANTIBODIES				
		IgM-VCA	IgG-VCA	EA-D	EA-R	EBNA
Susceptible	—	—	—	—	—	—

Reactivation	—	—	+++ /++++	— ^d	++ /+++	- /+++
immunosuppressed/ immunocompromised						
Burkitt lymphoma	—	—	+++ /++++	— ^d	++ /+++	+ /++
Nasopharyngeal carcinoma	—	—	+++ /++++	++ /+++	— ^e	++ /+++

^aAntibody response scale is none or negative (—), low (+), average (++), above average (+++), and very high (++++). A scale is used for application to various antibody tests and techniques. This table is modified from numerous studies. Individual responses outside the characteristic range may occur.

^bChildren younger than 4 years may have weak or undetectable heterophile antibody responses as determined by qualitative rapid slide tests.

^cIn some young children and in adults with asymptomatic seroconversion, the anti-EA response may be mainly to the EA-R component.

^dA minority of individuals will have the anti-EA response mainly to the EA-D component.

^eA minority of individuals will have the anti-EA response mainly to the EA-R component.

compartments and lesions (see next section) is of growing diagnostic importance in these circumstances.

Epstein-Barr Virus Nucleic Acid (DNA or RNA)

In young patients, EBV serologic testing may reveal false-positive results owing to retained maternal antibodies from the placenta, excessive blood product infusions, or asymptomatic seroconversion. In patients treated with immunosuppressants, a false-negative serologic response to EBV antigens may occur. In such situations, demonstrating EBV nucleic acid in tissue sections or in blood may be necessary for diagnostic purposes.¹² Methods include Southern blotting, in situ hybridization, and detection of EBV DNA by PCR.⁶⁹ Besides their utility as diagnostic aids, these tests also are useful for epidemiologic and pathogenetic purposes relevant to EBV infections.

Southern blot hybridization has been useful in demonstrating the association of EBV with disease.^{18,69,659} Although it is not as sensitive as PCR, Southern blotting has the advantages of providing additional information about the monoclonality of EBV-associated lesions, detecting lytic EBV processes, and recognizing viral integration into the genome.^{233,244,247,519}

Because of their ubiquity in EBV-infected cells (up to 10⁷ copies per cell), detection of EBERs in tissues by in situ RNA hybridization has become a standard method for detecting and localizing latent EBV in tissues.^{44,243,415} Probes for detection of EBERs (riboprobes) are labeled conveniently by immunoperoxidase methods. Detection of EBV DNA by in situ hybridization also can be performed,⁶⁷ although DNA detection is less sensitive because of the lower copy numbers per cell in comparison with EBERs.

Amplification of EBV DNA by PCR has emerged as an important test for establishing the diagnosis and treatment of several EBV-associated diseases. In adult patients with AIDS and primary CNS lymphomas, detection of EBV DNA in CSF has high sensitivity and specificity in most studies.^{22,113,415,442} PCR for EBV in CSF, possibly in combination with certain imaging studies,^{22,301} may be sufficient to establish the diagnosis of CNS lymphoma and could preclude performance of brain biopsy, which can be associated with complications. On the other hand, lumbar puncture in patients with cerebral lesions also must be considered carefully because of the risk for cerebral herniation.

In stem cell and solid-organ transplant recipients, quantitative PCR for EBV DNA in peripheral blood serves as a useful tool for the diagnosis of PTLT and as a marker during follow-up.^{232,388,645,680} Levels of EBV DNA in blood typically are low in healthy control subjects, high in those with PTLT or other EBV-associated diseases, and intermediate in asymptomatic organ transplant patients. A high EBV load in the blood has a clear relationship with development of PTLT,²³⁰ and with successful management, EBV DNA concentrations typically diminish

to baseline levels.^{230,294,538} Although negative predictive values for these tests are higher than 90%, positive predictive values are substantially lower. Healthy subjects with IM, asymptomatic seroconverters, and transplant recipients with PTLT may have comparably high levels of EBV detected in the blood, thus making it difficult to separate out true PTLT from increases unassociated with PTLT. Detection of EBV within cellular specimens, such as whole blood or peripheral blood mononuclear cells, appears to be more reproducible and accurate than are tests measuring cell-free EBV in plasma or serum. Further studies clearly are necessary to establish quantitative laboratory standards for diagnosis and monitoring of EBV-associated PTLT. Histopathologic evaluation of a suspicious tumor site is much more informative and less controversial regarding diagnostic utility.

Quantitative PCR also may be useful for diagnosis and monitoring of other EBV-associated malignant diseases, including NPC,³⁸² HL,³⁸⁹ and NHL.⁵⁹⁰ Larger studies are necessary to define better the role of EBV viral load testing in these diseases. PCR testing may also be of assistance in the laboratory testing for EBV-induced disease (as IM) in young children and infants.^{103,146} A systematic review on the performance of a quantitative real-time PCR assay for the detection of EBV DNA in immunocompetent children and young adults showed a pooled sensitivity of 77% and a pooled specificity of 98%.^{323,504}

Epstein-Barr Virus Proteins

Immunofluorescent techniques may be used to detect the presence of cells carrying EBV proteins in touch imprints of biopsy material or in frozen sections of cryopreserved tissue.^{233,415,507,685} Most commonly, tissues are examined for VCA, EBNA-1, and LMP-1 proteins with the use of mouse monoclonal antibodies.

Virus Isolation

EBV from blood or oropharyngeal specimens (rarely, other specimens) can be isolated in tissue culture with a transformation assay.³¹⁸ For oropharyngeal specimens, the test requires incubation with fresh cord blood mononuclear cells for as long as 6 weeks. Transforming virus can be identified in peripheral blood by incubating mononuclear cells in the presence of cyclosporine (for inhibition of cytotoxic T cells, which can suppress the growth of EBV-positive B cells). An end-point dilution assay may be used to quantitate the amount of EBV within blood specimens.⁵³⁷ Virus isolation tests are used primarily for research purposes and are not widely available.

Electron Microscopy

EBV virions also may be detected by electron microscopy, which has been used in patients with oral hairy leukoplakia,³¹¹ NPC,²⁵ and other EBV-associated lesions. The ultrastructural features of EBV virions,

however, are indistinguishable from those of other herpesviruses, and confirmatory tests usually are necessary. Electron microscopy generally is available only at larger research centers and therefore is impractical for routine diagnostic testing.

Imaging Studies

Imaging studies seldom are necessary in typical patients with IM. In one study of patients hospitalized with IM, the most common findings on chest radiography were splenomegaly (47%), hilar adenopathy (13%), and interstitial infiltrates (5%).³⁷⁷ Imaging studies are used more commonly for evaluation of EBV-associated neurologic disease, especially in immunocompromised patients. Children with EBV-associated encephalitis usually have normal neuroimaging results.¹⁴⁴ However, some patients may display diffuse swelling or patchy low-density lesions by computed tomography, and magnetic resonance imaging (MRI) may reveal increased signal on T2-weighted images as well as atrophy.^{144,565} Involvement of one or more anatomic locations of the brain in children with encephalitis may be seen on MRI, including cerebral hemispheres, basal ganglia, cerebellum, brain stem, and thalamus. The most common site of isolated involvement is the cerebellum.² Contrast-enhanced computed tomography scans of primary cerebral lymphoma in patients with AIDS typically reveal large (2 to 6 mm) lesions occurring anywhere in the cerebrum with diffuse and homogeneous enhancement⁶¹⁰; however, some overlap exists with findings observed in other diseases, such as cerebral toxoplasmosis. Thallium-201 single-photon emission computed tomography, in conjunction with magnetic resonance imaging and PCR testing of CSF for EBV DNA, may be useful in distinguishing CNS lymphomas from toxoplasmosis in adult patients with AIDS.^{22,301}

Differential Diagnosis

Infectious Mononucleosis

EBV causes an estimated 80% to 95% of IM syndromes.^{170,375} Numerous agents have been associated with heterophile-negative IM. CMV is responsible for most cases of heterophile-negative IM with typical clinical and hematologic findings.²⁹³ Certain features of CMV mononucleosis may help distinguish it from EBV (e.g., less common sore throat and lymphadenopathy, less intense atypical lymphocytosis, and prominent splenomegaly), but these characteristics have considerable overlap with EBV-associated IM. Serologic testing consistent with acute CMV infection in the absence of characteristic EBV serologic findings confirms the diagnosis.³⁷⁵ The remainder of cases may be attributable to infection with *Toxoplasma gondii*, adenoviruses, rubella virus, or hepatitis A virus. Acute HIV syndrome also may mimic IM. However, in children with non-EBV IM, the etiology frequently remains elusive. In heterophile-negative children with mononucleosis and both the clinical and hematologic characteristics of the syndrome, the most likely known agents are EBV and CMV.

Other EBV-Associated Disorders

EBV-associated HLH may be confused with IM, systemic connective tissue disorders, septicemia, and certain hematologic malignant neoplasms.³⁰⁴ EBV-associated CNS lymphomas in adults with AIDS are difficult to distinguish from cerebral toxoplasmosis on the basis of clinical findings and imaging studies. Historically, a negative *T. gondii* serum antibody test response eliminates toxoplasmosis, whereas a positive test response may necessitate a trial of antitoxoplasmic therapy. Response within a week suggests toxoplasmosis, but a nonresponse indicates the need for stereotactic brain biopsy to establish a diagnosis. Identification of EBV DNA in CSF by PCR may help confirm the diagnosis of lymphoma.³⁰¹ Because PTLDs may affect the graft, a high EBV viral load in conjunction with graft abnormalities (e.g., elevated liver enzyme values in a liver transplant recipient) may be confused with graft rejection; histologic evaluation of biopsy tissue from the graft should differentiate PTLD from acute graft rejection.

TREATMENT

Infectious Mononucleosis

Supportive Care

Support, including rest, fluids, and antipyretics, is all that is required for uncomplicated IM. Although clinical trials and case reports dating

to the 1950s generally have demonstrated a beneficial effect of short-term use of corticosteroids in patients with severe symptoms (e.g., high fever, severe pharyngitis),^{16,49,66} a recent systematic review concluded that there is insufficient evidence of the efficacy of steroids for symptom improvement in patients with IM.⁵²⁶ Furthermore, some studies have shown adverse effects of such therapy, including respiratory distress, neurologic complications, secondary bacterial infections, and acute-onset diabetes.^{221,526,647} Although little controversy exists about the use of corticosteroids for patients with complicated illnesses (e.g., with stridor from massively enlarged tonsils or paratracheal adenopathy, or for those with hematologic or neurologic complications; see [Complications of Infectious Mononucleosis](#) earlier), personal experience and clinical judgment largely dictate the use of corticosteroids in practice.^{142,622} For example, in a report of patients with IM evaluated as outpatients and inpatients, 45% received systemic corticosteroids, with only a small proportion (<10%) of these patients having airway concerns.⁶²²

Antiviral Treatment

Numerous antiviral agents inhibit replication of EBV in vitro. Such agents include acyclovir, famciclovir, penciclovir, ganciclovir, and other nucleoside analogues.^{33,118,132,222,404,586} None of these agents is capable of eliminating latent EBV present as episomes in infected cells. Five randomized, placebo-controlled trials of acyclovir (with or without corticosteroids) in adolescents and adults with IM demonstrated no beneficial effect in resolving the clinical signs and symptoms associated with illness as well as no reduced rate of complications.^{15,17,476,635,637} Moreover, a meta-analysis substantiated these findings.⁶²⁹ Acyclovir did significantly reduce the rate of EBV shedding in the oropharynx, albeit temporarily.⁶²⁹ A study reported a decrease in the quantity of EBV DNA in oral washings and blood as well as in illness severity during treatment with valacyclovir.⁶⁴²

Epstein-Barr Virus-Associated Malignant Diseases

Providing details about treatment of EBV-associated lymphoproliferative diseases, including lymphomas, is beyond the scope of this chapter. Pediatric oncologists must be involved in the care of children with these malignant diseases. A brief overview of treatment of the principal diseases is provided.

Posttransplant Lymphoproliferative Disease

The most effective therapy for PTLT in transplant recipients is reduction (or complete elimination)³⁰⁰ of immunosuppression to allow more effective control of rampant EBV infection by the cell-mediated immune system. This measure halts progression of PTLT in approximately two thirds of pediatric solid-organ transplant recipients developing polymorphic PTLT in the first year after undergoing transplantation.²³² Decisions concerning reduction of immunosuppression must be weighed against the risk of graft rejection, and careful follow-up with frequent EBV viral load measurements must be ensured. If no improvement occurs after a trial of reduced immune suppression, other therapeutic modalities must be considered singly or in combination.

Although antiviral agents (acyclovir, ganciclovir, valganciclovir) are used frequently for PTLT, largely on the basis of an anecdotal report published in 1982,²⁶¹ no clinical trials have confirmed their efficacy. Because these agents treat lytic EBV infections, yet PTLT primarily involves latent virus, the consensus has been that these agents should have minimal impact on PTLT. However, this view has been challenged by reports in experimental animals suggesting that the small proportion of lytically infected cells within these tumors may contribute to the growth of EBV-associated malignant lesions by enhancing angiogenesis and inducing paracrine B-cell growth factors.^{289,290}

There is now considerable experience with the use of rituximab, a chimeric monoclonal antibody directed at CD20, against PTLT.^{217,240,630} Although no randomized controlled clinical trials have been conducted to date in children, data from cohort studies, case reports, and a phase II trial indicate that rituximab is safe and effective.^{217,240} Most adverse events are mild or moderate and usually are related to the first infusion of the antibody. Despite a profound reduction of circulating B cells in peripheral blood, hypogammaglobulinemia is an uncommon occurrence with rituximab treatment (although more likely in young children),

and patients are not at higher risk for development of infectious complications. Most centers now use rituximab as a primary therapeutic agent for PTLD if reduction of immune suppression is unsuccessful.

IFN- α has induced complete remissions in some studies,^{134,398} but relapses and graft rejections have occurred. Conventional NHL chemotherapy (CHOP regimen) consisting of cyclophosphamide, daunorubicin, vincristine, and prednisone may have increased toxicity and mortality associated with infection when standard doses are used,^{454,586,608} thus leading to investigation of low-dose CHOP regimens consisting of cyclophosphamide and prednisone.^{41,239}

Experimental therapy using EBV-specific cytotoxic T lymphocytes has been successful for PTLD in human stem cell transplant recipients,⁵⁴¹ but it is more complicated for solid-organ transplant recipients with PTLD. In contrast to stem cell transplant recipients, whose EBV-associated PTLD tumors are derived from the donor, tumors in solid-organ transplant recipients are invariably derived from the recipient. Therefore, EBV-specific cytotoxic T lymphocytes must be prepared by ex vivo EBV transformation of either the recipient's B cells^{62,213,351} or at least partially HLA-matched banked B cells.²⁶³ Surgery and radiation therapy generally are reserved for local complications of tumors, including compression of an airway or gastrointestinal bleeding,²³² but they have been used more widely at some institutions.¹¹⁹ A multifaceted approach, such as that used by Comoli and colleagues,¹¹⁹ ultimately may yield the highest response rates against the most aggressive forms of PTLD. Clinical trials of cytotoxic T lymphocytes as prophylaxis and treatment of PTLD continue to show promising results.^{62,213}

B-Cell Lymphoma

Endemic (African) BLs, which are highly associated with EBV,³⁷¹ are treated primarily with cyclophosphamide-based chemotherapy.^{372,690} Favorable responses were observed by Labrecque and coworkers³⁷² in patients with tumors expressing lytic genes. Treatment of sporadic BL also is based primarily on multiagent chemotherapy that includes cyclophosphamide.⁴⁰¹ Case reports have indicated positive responses to rituximab, and Children's Oncology Group protocols now include rituximab as first-line treatment of BL.²¹⁷

B-cell lymphomas in patients with AIDS are extremely difficult to treat, primarily because of the underlying severe host immune deficiency. Early regimens using standard chemotherapeutic regimens were largely failures, with survival rates lower than those of untreated patients; most patients died of opportunistic infections, drug toxicity, and resistant tumors. Alternative therapeutic strategies have improved outcomes for this malignant disease, yet mortality rates remain substantial.⁴⁰⁸ These strategies have included lower doses of standard drugs,³³⁸ hematopoietic growth factors,³⁷⁹ novel immunotherapies (e.g., interleukin-2),⁵⁰ and adoptive immunotherapy,⁶⁶¹ as well as improved management of opportunistic infections and HIV infection. In vitro data indicate the effectiveness of anti-NF- κ B treatments, including bortezomib⁶⁹² and certain statin drugs,³⁴² and the hope is that human studies will follow. An exciting emerging area of therapy is termed lytic induction and involves treatment of EBV-positive lymphoma cells with certain agents that induce a transition from latent to lytic infection, thus rendering them susceptible to antiviral therapy (e.g., ganciclovir, zidovudine).^{47,129}

AIDS-related primary CNS lymphomas are extremely difficult to treat. Historically, palliative whole-brain radiation therapy in conjunction with corticosteroids was used for treatment, but with disappointing survival rates of only a few months. Combined modality therapy with whole-brain radiation and chemotherapy has been investigated but generally also produces poor outcomes.³³⁹ However, most studies were conducted before wide availability of cART. A minority of healthier patients with AIDS may respond better to combined modality regimens.³³⁹ For patients not already receiving cART, initiation of an appropriate regimen is recommended, because case reports have described improvement. The use of ganciclovir has been shown to decrease EBV DNA load in CSF and improve survival in adult patients with HIV-related primary CNS lymphoma.⁶⁵

Hodgkin Lymphoma

Historically, children with HL were treated with high-dose radiation. However, high rates of skeletal growth inhibition and secondary malignant

neoplasms were noted in survivors, so new trials using lower involved-field radiation in conjunction with multiagent chemotherapy were conducted. These trials form the basis for combination treatment regimens used currently in growing children.^{298,511} Although the presence of EBV in tumor (more likely in mixed-cellularity types) currently plays no role in pretreatment staging, some studies suggest improved outcomes for patients with EBV-positive tumors.^{445,451} However, the presence of pretreatment EBV DNA in peripheral blood has been linked with poor outcomes in patients with HL.⁴⁸³

Nasopharyngeal Carcinoma

NPCs are sensitive to radiotherapy as well as to chemotherapy. Surgery usually is not an option because of the location of the primary tumor, although it may be necessary for persistent or recurrent lymph node disease. For early localized disease, radiotherapy generally is indicated, whereas combined modality treatment (radiation and chemotherapy) may be considered for more advanced disease.^{5,29} Children whose treatment is failing have a high rate of distant metastases, principally to bone.^{28,305}

Nonmalignant Epstein-Barr Virus-Associated Diseases

XLP

In an effort to prevent fulminant IM, intravenous immune globulin is recommended for patients with XLP who display hypogammaglobulinemia, although such therapy is not fully effective.²⁰⁷ Traditional therapy with antivirals and IFN- α has been disappointing for fulminant IM, but reported success with rituximab (in combination with corticosteroids and other agents) has provided some enthusiasm.^{440,452} Males with XLP also can develop lymphomas, which may respond to traditional chemotherapy regimens. Presently, the only definitive cure for XLP is allogeneic hematopoietic stem cell transplantation. Fifteen such transplants were reported between 1986 and 2005, with 10 survivors.³⁷⁸ Younger age appears to be associated with improved survival in this limited population. Administration of rituximab may be considered a bridge between the diagnosis of XLP and transplantation.^{378,563} Now that the gene defect in XLP has been identified, consideration may be given to a gene therapeutic approach.⁴⁴⁰

HLH

Early studies using non-etoposide-containing regimens were largely unsuccessful in significantly reducing the high mortality rate associated with HLH.²³ Chemotherapeutic regimens including etoposide (toxic to macrophages) have reduced the mortality rate significantly. Results of a standardized protocol (HLH-94) developed by the Histiocyte Society have been published.^{275,631} Agents in this protocol included etoposide and corticosteroids for initial therapy, followed by etoposide, corticosteroids, and cyclosporine (continuation therapy), leading to *Bone Marrow Transplant*. Patients with CNS involvement, as determined by symptomatology, CSF analysis, or MRI results, also should receive intrathecal chemotherapy with methotrexate and hydrocortisone. A similar standardized protocol (HLH-2004), but including cyclosporine at initiation, currently is being evaluated.³¹⁴ Few data are available on salvage therapy for children unresponsive to the HLH-94 protocol, but Janka³¹⁴ has summarized anecdotal successes with standard NHL or HL treatment protocols, some monoclonal antibodies (e.g., anti-CD25 and anti-CD52), and treatment with fludarabine (an antiviral agent) of one child who survived until bone marrow transplantation could be performed. For patients with EBV-induced HLH, most experts recommend the use of rituximab 375 mg/m² weekly for 1 to 4 weeks.^{99,333,440} Chellapandian and colleagues showed improved symptoms, reduced EBV viral loads, and decreased inflammation in patients with EBV-induced HLH when rituximab was added to the standard treatment.⁹⁹

CAEBV Infection

Treatment modalities for CAEBV infection have varied widely, because the rarity of this disease precludes performing proper clinical trials. Resolution of symptoms has been reported in case reports with use of antiviral drugs (e.g., acyclovir, ganciclovir),³⁰⁷ etoposide,⁴⁷⁰ immunomodulatory agents (e.g., corticosteroids, intravenous immune globulin, cytokines),^{191,201,346} adoptive transfer of cytotoxic T cells,⁵⁵⁶ or

combinations thereof. For the most severe forms of disease, stem cell transplantation may be considered.⁴⁶⁹

HIV-Associated Diseases

Oral hairy leukoplakia generally does not require therapy because patients typically are asymptomatic and the lesions have no malignant potential. However, therapy may be required for troubling symptoms or cosmetic or psychological reasons. Small lesions may be treated topically,⁴⁴⁶ but large lesions require systemic oral antiherpetic virus agents.⁴⁸⁴ Treatment strategies for LIP are not defined well. Supportive care, including supplemental oxygen, may be necessary. Suppression of HIV with effective antiretroviral agents also is logical to improve immune function and to minimize the potential direct effect of HIV infection. Although no controlled studies have documented the value of antiretrovirals, benefit is suggested by the declining prevalence of LIP in children during the cART era.²²⁵ Corticosteroids also may be of benefit.^{21,433} Some reports suggest benefit of chloroquine therapy in children with LIP with and without HIV infection.^{79,653} No controlled studies have evaluated antiherpetic virus drugs (e.g., acyclovir) for LIP.

PROGNOSIS

The prognosis for healthy persons with IM is extremely good, with mortality considered a rare occurrence. In a series of 30 fatal cases of IM from the 1950s, Lukes and Cox⁴¹² found splenic rupture, Guillain-Barré syndrome, hemorrhage, and secondary infection to be the most common causes of death. In Penman's⁴⁹⁴ later study of 20 documented deaths, predominantly of young adults, the causes of death (in decreasing order of frequency) were neurologic complications, splenic rupture, secondary infection, hepatic failure, and myocarditis. EBV-induced aplastic anemia, a rare but dreaded hematologic complication, now is thought to have a better prognosis for eventual recovery if the patient can be supported successfully through the acute stages.^{43,380} It has been suggested that older patients are at higher risk for severe EBV-related IM.⁶¹⁶

The prognosis for patients with EBV-associated lymphoproliferative diseases is variable and depends on the immunologic status of the patient and the type of lymphoproliferation. A registry of 161 males with XLP indicated a mortality rate of 70% by the age of 10 years and 100% by the age of 40 years.²³⁵ HLH has a greater than 90% fatality rate without treatment; most deaths are caused by hemorrhage, overwhelming infection, disseminated intravascular coagulation, or multi-organ failure.^{101,315} Etoposide-based treatment has improved outcomes considerably.³¹⁴ The median survival rate was 54% at 6 years follow-up in patients treated on the HLH-94 protocol. Patients without neurological involvement and those older than 6 months had higher survival rates (approximately 65%).^{275,631} The largest case series of CAEBV infection (from Japan), which included 21 children younger than 18 years, reported a mortality rate of approximately 30% despite various forms of therapy.³⁵⁸ Historically, PTLTD that develops after solid-organ transplantation has carried a relatively high mortality rate (50–80%), with higher mortality rates in bone marrow transplant recipients.¹⁷⁸ Presently, the mortality rate is probably much lower, but more time is necessary to assess the impact of newer therapeutic modalities. The prognosis for healthy children with NHL generally is good, with 5-year relative survival rates of 80%.⁵³² However, the prognosis for patients with AIDS and NHL is poor. In adults with AIDS, median survival is 2 to 4 months for CNS lymphomas (virtually all of which are EBV associated), with only slightly longer survival noted in patients receiving cART.³³⁹ Childhood HL generally has a very good prognosis, with 5-year survival rates of approximately 95%.⁵³² With use of combined modality therapy, children with NPC have long-term survival rates in the range of 70% to 90%.²⁹

PREVENTION

EBV is shed regularly in saliva, and therefore infection control policies are difficult to develop. In addition, mechanisms for EBV transmission are not well understood, and EBV outbreaks occur rarely if at all. For these reasons, no more than standard infection control precautions are recommended for patients hospitalized with EBV infections, including IM.³⁵⁴ Although transfusion-associated EBV infection occurs rarely,

persons with recent EBV infection of mononucleosis-like illnesses are urged to refrain from donating blood or organs.³⁵⁴ Because EBV is spread through salivary contact, individuals should avoid sharing food and drinks, especially with someone known to have had a recent EBV infection, if they wish to reduce the risk of acquiring EBV.

Vaccine

Efforts continue in the development of an EBV vaccine. Because of concern about the administration of a vaccine with unknown long-term consequences, including malignant transformation, most efforts have been focused on development of subunit EBV vaccines. A subunit vaccine containing the EBV gp350 protein has proved effective in preventing EBV infection in an experimental animal model.^{163,574} A vaccinia virus-based gp350 vaccine has been evaluated in a small number of Chinese patients, eliciting good antibody responses and providing some protection from EBV infection²⁴²; however, these findings were not corroborated, and this vaccine was not developed further. A recombinant gp350 vaccine with adjuvant has been evaluated in Belgium, with phase I and phase II data published.^{447,585} The vaccine was immunogenic, safe, and well tolerated. Although vaccine recipients were not protected from EBV infection, symptoms of IM were reduced compared with controls.^{410,585}

The EBV vaccine may soon enter phase III trials.⁵¹⁴ An effective vaccine could be considered for persons at high risk for development of EBV-associated lymphoproliferative disease and cancer, such as patients with AIDS, those with XLP, and organ or stem cell transplant recipients. Before such a vaccine is approved, further research must be conducted to address issues such as protection against exogenous superinfection from wild-type EBV strains.⁶⁴⁹ Therapeutic vaccines, aimed primarily at latent antigens expressed in EBV-associated malignant diseases such as NPC, also are under investigation.^{154,403,573} Virus-like particle-based EBV vaccine candidates are also in preclinical development.⁵⁴⁸

Prevention of Posttransplant Lymphoproliferative Disease

Strategies for prevention of PTLTD reflect many of those used for treatment of established PTLTD (see earlier section on treatment of PTLTD).⁴⁴⁰ Children at high risk for development of PTLTD (e.g., EBV-seronegative children and infants younger than 12 months) typically are given prophylactic anti-CMV immune globulin and an antiviral after transplantation. A retrospective analysis of a large renal transplant database covering Europe and North America (96% adults) has suggested a beneficial effect of anti-CMV immune globulin (e.g., CytoGam) in the prevention of B-cell lymphomas.⁴⁷³

After undergoing transplantation, these children should have frequent EBV viral load testing. If EBV viral loads persist above a significant cutoff value established by the laboratory, preemptive measures should be considered. Although real-time PCR tests are sensitive in predicting development of PTLTD, they are not highly specific and lack standardization. Cutoff values for "significant" concentrations of EBV DNA vary from laboratory to laboratory. Once a decision is made that preemptive therapy is warranted, reduction or elimination of immunosuppressive medications should be performed. In addition, rituximab treatment administered preemptively in patients who have significant viremia (>40,000 copies/mL in blood) may respond with resolution of viremia, without development of PTLTD.⁶⁷⁴

Adoptive transfer of cytotoxic T lymphocytes specific for EBV, produced from donor peripheral blood mononuclear cells stimulated with EBV target antigens, is also under clinical development as an antiviral prophylactic agent as well as an antiviral treatment agent for EBV-expressing lymphoproliferative diseases in allogeneic hematopoietic stem cell transplant recipients.^{62,213}

Before 1986, five human herpesviruses (HHVs) were known. They were herpes simplex virus (HSV) type 1 (oral) and type 2 (genital), cytomegalovirus (CMV), varicella-zoster virus (VZV), and Epstein-Barr virus (EBV). The herpesviruses are important pathogens causing a variety of childhood diseases that are described in other chapters of this text. An inherent characteristic of herpesviruses is their ability to form a latent infection, in which the viral genome continues to reside within the host. When the virus reactivates, it often causes further symptoms and signs. Thus, herpesviruses cause a spectrum of illnesses during the lifetime of the infected human host.

During the last decades of the 20th century, three novel herpesviruses were discovered. Two of these were originally designated HHV-6 and HHV-7, whereas the newest member of the family has been called either Kaposi sarcoma-associated herpesvirus (KSHV) or HHV-8. In 2012, the decision was made to separate HHV-6 into two distinct species called HHV-6A and HHV-6B. These viruses and the diseases they cause are described in this chapter. A point of particular interest for pediatric infectious disease is the increasingly convincing association of HHV-6B infection with febrile seizures and subsequent epilepsy.

HUMAN HERPESVIRUSES 6A, 6B, AND 7

One unexpected consequence of the epidemic of acquired immunodeficiency syndrome (AIDS) was the discovery of a new human DNA virus. The virus was isolated first from the white blood cells of six patients with lymphoproliferative disorders, two of whom had AIDS.²⁷ Further electron microscopic characterization of the virus demonstrated properties of a herpesvirus, including (1) an icosahedral capsid composed of 162 capsomers covered by a lipid membrane and (2) an enveloped particle with a diameter of 200 nm (Fig. 161.1). Because the virus was isolated originally from B lymphocytes, the agent was designated human B-lymphotropic virus. However, this apparent tropism for B lymphocytes was not confirmed by other investigators, who found that the virus preferentially infected CD4 T lymphocytes and not B lymphocytes.^{20,30} Thus, the initial designation of human B-lymphotropic virus was changed to HHV-6.

The DNA sequence and the deduced amino acid sequence of the HHV-6 genome have been published.⁶ Calculation of the percentage of amino acid identity shared by HHV-6 proteins with those in other herpesviruses revealed that HHV-6 proteins most closely resembled those of human CMV. The strains of HHV-6 have been divided into group A and group B. The HHV-6 isolates related to prototype strain U1102 have been called group A, whereas those related to strain Z29 have been designated group B. The genomes of the group A and B viruses exhibit a 90% nucleotide sequence identity. In 1990, while searching for additional strains of HHV-6, Frenkel and coworkers¹⁴ isolated a new T-lymphotropic herpesvirus that was designated HHV-7. HHV-7 is related closely at a genetic level to HHV-6 and to a lesser degree to CMV.⁶ In 2012, the International Committee on Taxonomy of Viruses decided to designate HHV-6A and HHV-6B as distinct species.¹ Thus, there are now nine human herpesviruses.

Most people contract their primary HHV-6 infection before reaching the age of 5 years.³ In the United States, primary HHV-6 infection occurred in 40% of children by the time they reached 12 months of age and in 77% by the age of 24 months.⁴¹ In these young children, HHV-6 strains (now known to be mainly HHV-6B) appear to be a major cause of the disease roseola (exanthem subitum). Roseola is discussed in Chapter 59. Children also may contract a primary HHV-6 infection without manifesting a rash. After acute infection, HHV-6 forms a latent infection, probably in T lymphocytes. In a small number

of infants, acute HHV-7 infection appears to cause a roseola illness much like that of acute HHV-6 infection.¹⁷

Diseases Caused by HHV-6A, HHV-6B, and HHV-7

Studies in Japan first delineated the nature of the illness associated with acute HHV-6 infection in young children.³⁹ HHV-6 was cultured from the peripheral blood leukocytes of four infants with roseola (exanthem subitum); each subject was 6 months old and had an acute febrile illness followed by a concurrent fall in temperature and the onset of a rash. The blood samples were collected during the febrile stage of the disease. In a subsequent paper by the same group, two infants (6 and 7 months of age) were described who developed HHV-6 infection *without* a rash.²⁹ Both infants had been seen by physicians because of a 2- to 3-day history of high temperature (38.5–39.5°C). The only abnormal clinical finding was congestion of the throat. In both cases, the temperature rapidly returned to normal around day 3 of illness, but no rash was ever observed. Cultures of peripheral blood cells from both infants were positive for HHV-6.²⁹ Further seroprevalence studies performed in Japan showed that most Japanese children (86%) contracted HHV-6 infection by the time they were 24 months of age.⁴⁰ Thereafter, the increase in seropositivity among the childhood populations was small. These statistics suggest that HHV-6 infection goes unrecognized in most children.

Primary HHV-6 infection has been implicated in a few cases of severe hepatitis. The first case was that of a 21-year-old patient with cystic fibrosis who received a liver transplant.³⁶ The recipient lacked antibodies to HHV-6, and the organ donor was seropositive. Two weeks after undergoing transplantation, the recipient developed fever and grand mal seizures; her hepatic function deteriorated. HHV-6 was cultured from her peripheral blood cells. The apparent source of infection was the donor liver, from which HHV-6 presumably was reactivated after transplantation. She gradually recovered her hepatic function during the course of several weeks.

A fatal case of fulminant HHV-6 hepatitis has been reported in a 3-month-old boy.⁴ The infant was admitted to a hospital because of fever, jaundice, convulsions, and loss of consciousness. His serum bilirubin concentration, liver transaminases, and blood ammonia level were elevated markedly. Within 7 days, he became comatose and died. As part of the diagnostic evaluation, HHV-6 was cultured from his mononuclear cells. Furthermore, HHV-6 DNA was detected in biopsy samples of liver and brain, which were obtained immediately after death.

In a large retrospective review of roseola in association with acute HHV-6 infection, the signs and symptoms were tabulated.³ The study population included 94 boys and 82 girls, who ranged in age from 3 weeks to 18 months (Table 161.1). As would be predicted, the two most common clinical findings were fever and rash. The temperature often rose to 39°C, and fever persisted for 2 to 4 days. The rash usually appeared when the fever lessened; the rash was papular in 54%, macular in 40%, and maculopapular in the remainder of the children. The exanthem typically persisted for 3 to 4 days and was not followed by desquamation. Diarrhea was a surprisingly frequent occurrence, but it was not severe. An enanthem called *Nagayama spots* in Japan consisted of papules on the mucosa of the soft palate and uvula. Of the total study group, 8% developed febrile seizures. More severe central nervous system (CNS) complications have been documented in children not enrolled in this study. A few children with HHV-6 encephalitis have had abnormal electroencephalographic recordings. Some children with encephalitis have had permanent neurologic sequelae. In the United States in particular, acute HHV-6 infection also appears to be associated with concurrent acute otitis media.²⁴

Modified from Asano Y, Grose C. Human herpesvirus type 6 infections. In: Glaser R, Jones J, eds. *Herpesvirus Infections*. New York: Marcel Dekker; 1994:227-244.

Reactivation of previous HHV-6 infection has been demonstrated in some healthy children and adults who contracted a second herpes-type infection, such as primary EBV infection (infectious mononucleosis) or primary CMV infection.³ A similar serologic survey was performed in 10 renal transplant recipients who initially were HHV-6 seropositive.³ After transplantation, all 10 showed greater than fourfold rises in antibody to HHV-6. Only two of the 10 developed a febrile illness, and both of them also had primary CMV infection.

Among the human herpesviruses, HHV-6 infections are unique in that HHV-6 DNA is integrated into the subtelomeric region of chromosomes in about 1% of the adult population.¹ In a recent survey of 21 cases of integrated HHV-6 infection following transplantation, HHV-6B DNA was found more often among solid organ transplant recipients, whereas integrated HHV-6A was more common among allogeneic hematopoietic stem cell recipients. None of the 21 transplant patients developed clinical symptoms related to the integrated HHV-6 infections.¹⁸ Furthermore, HHV-6 infection is not related causally to Kawasaki disease, nor does HHV-6 infection appear to alter the course of human immunodeficiency virus (HIV) infection.²⁸

Whether HHV-7 causes a distinct illness has been the subject of many medical investigations since 1990. In general, HHV-7 antibody is acquired by mid-childhood, but there appears to be no corresponding sentinel illness. However, in two infants with roseola, both isolation of HHV-7 and seroconversion to HHV-7 were documented; in addition, another five children with roseola were found to have undergone seroconversion to HHV-7.³² HHV-7 also has been isolated from one infant with an acute febrile illness.²⁵ Therefore, in a small number of young children, acute HHV-7 infection may be associated with fever and sometimes a roseola-like rash.

Finally, congenital infections also can occur in pregnant women already infected with HHV-6. In a survey of 5638 cord blood samples, HHV-6 DNA was detected in 57 samples (1%), but the congenital infections did not cause an identifiable disease in the newborn.¹⁶ Of great interest, congenital HHV-6 infections appear to be caused mainly by chromosomally integrated HHV-6 DNA. Therefore, the HHV-6 genome will be present in all cell types, including tissues in the central nervous system of the newborn. Chromosomal integration during congenital infection appears to occur more commonly with HHV-6A than with HHV-6B strains.

Neurologic Complications

In the preceding paragraphs, CNS symptoms were mentioned briefly. In a large series of clinical studies performed in Japan, seizures were a common feature of acute HHV-6 infection.^{3,37} In one series of 105 young children with acute febrile convulsions, 21 had evidence of primary HHV-6 infection, as assayed by either isolation of virus from blood or seroconversion of HHV-6 antibodies. When the age of the patient was assessed, HHV-6 infection was found in 13 of 23 seizure patients younger than 1 year; thus, the seizure group with HHV-6 infection was significantly younger than the seizure group without HHV-6 infection. In addition, the frequency of clustering seizures, long-lasting seizures, partial seizures, and postictal paralysis in children having their first febrile convulsion episode was significantly higher in those with primary HHV-6 infection than in those without HHV-6 infection. One child with fatal acute necrotizing encephalitis and concurrent HHV-6 infection also has been described.²²

In early studies from Japan, assays for HHV-6 and HHV-7 DNA were performed on cerebrospinal fluid samples from 43 children with CNS symptoms.³⁸ All children had symptoms compatible with aseptic meningitis. HHV-6 DNA was detected in the peripheral blood cells of 15 and in the cerebrospinal fluid of 7 children; all were HHV-6 variant B. HHV-7 DNA was detected in the peripheral blood cells of 28 and in the cerebrospinal fluid of 6 patients. Thus, the clinical study demonstrated that both HHV-6 and HHV-7 can invade the CNS or, alternatively, frequently reactivate within the CNS during childhood neurologic disease. The results from Japan have been confirmed in a similar large analysis of young children with seizures in Britain and Ireland.³⁵ Among 156 children hospitalized with febrile seizures, 26 (17%) were associated with acute HHV-6 or HHV-7 infection. The median age for hospitalization in the HHV-6 group was 53 weeks, and the median age for the HHV-7 group was 60 weeks. In turn, the prior results were again confirmed in a prospective study of 199 children between the ages of 1 month and 5 years from the United States, who presented with prolonged febrile seizures. Blood samples were tested for HHV-6A, HHV-6B and HHV-7 DNA and RNA. HHV-6B viremia was detected in 32% and HHV-7 viremia was detected in 7% of the children, whereas no child had HHV-6A viremia.¹³

HHV-6 infection is an important cause of post-transplant acute limbic encephalitis (PALE) after a hematopoietic stem cell transplantation. Among six children who underwent cord blood transplantation for hematological malignancies at one hospital in Australia, all six developed PALE in association with HHV-6 infection.¹⁷ Three patients developed confusion, general impairment of memory, and sporadic seizures. The other three had more severe symptoms, including generalized epilepsy that presented during the third week after the transplant. The diagnosis of HHV-6 infection was made by detection of viral DNA in blood and spinal fluid. The seizures were initially controlled and the HHV-6 infection was treated. However, after another 11 to 18 months, all three patients developed generalized seizures that were much more difficult

to control. All three patients experienced a severe regression in their motor and intellectual functioning. HHV-6B infection also may be an important cause of mesial temporal lobe epilepsy.¹⁸ HHV-6B DNA was detected in approximately one fourth of resected brain biopsies from patients with temporal lobe epilepsy. Several of these epilepsy patients had a history of febrile seizures earlier in childhood.

Pathogenesis of HHV-6 and HHV-7 Infection

The pathogenesis of HHV-6 infection certainly includes a viremia while the child is asymptomatic; the total duration of the incubation period is not well defined but may be approximately 10 days. Although these studies were performed before HHV-6A and HHV-6B were distinguished, it is now known that the vast majority of these cases in young children are caused by HHV-6B infection (roseola). The prodrome, which signals the end of the incubation period, includes 2 to 4 days of fever, which precedes the onset of the rash.^{3,26} During this period, virtually 100% of peripheral blood cell cultures are positive for HHV-6. By day 3 or 4, when the rash first appears, the viremia is abating. Between 5 and 7 days after the onset of the fever (or 2 to 4 days after appearance of exanthem), viremia persists in less than 20% of the children. Viremia is absent later in convalescence, when the antibody response is detectable. HHV-6 occasionally reactivates from latency throughout the lifetime of an infected human, but usually no apparent illness is present.⁷

The mothers of infants with HHV-6 infection have been studied to determine whether they are the source of the infectious agent.¹⁶ Because most mothers are seropositive, the possibility exists that HHV-6 infection could reactivate in the mother, who would then transmit the infection to her child, possibly through exchange of saliva. Obviously, mothers with an integrated HHV-6 DNA infection can pass the infection to their fetus during gestation.¹⁶ However, for mothers without an integrated infection but with HHV-6 seropositivity, HHV-6 DNA was detected in the vaginal secretions, so perinatal HHV-6 transmission remains a possibility. Older siblings are another possible source of infection within a household.⁴¹

In contrast with HHV-6, HHV-7 seropositivity occurs in children, but often after the first 2 years of life. HHV-7 transmission has been investigated in large multigenerational Japanese families living in the same household.³¹ The results indicated that HHV-7 is transmitted gradually from older generation to younger generation (Fig. 161.2). Transmission often occurs in children before the child enters a traditional primary school at the age of 6 years. Either parent or presumably an older sibling can transmit the virus. A reasonable explanation for this pattern of transmission is repeated exchange of infectious saliva among family members living in the same household during the course of many years.

Diagnosis

Infection with HHV-6 can be diagnosed by several means, including (1) measurement of antibody, (2) isolation of virus, (3) detection of viral antigen, and (4) detection of viral DNA. The first method (i.e., the traditional approach for diagnosis of virus infection) usually requires acute and convalescent serum samples for determination of a fourfold or greater rise in titer of virus-specific IgG antibody. The finding of IgM specific for HHV-6 in a single serum sample also would indicate an acute infection in a young child. HHV-6 antibodies usually have been measured by an indirect immunofluorescence method, although neutralization tests also have been performed.^{3,4,34}

Isolation of HHV-6 was the original technique for identification of this herpesvirus.²⁷ The method is more difficult to perform than are those methods commonly used for most herpesviruses (e.g., HSV, CMV, VZV) but is similar to that required for isolation of another herpesvirus, EBV. HHV-6 usually is isolated in a cell substrate consisting of mononuclear cells obtained from cord blood of a newborn infant. The source of virus in the patient also is the peripheral blood mononuclear cell population.³⁴

Viral genome can be detected in infected tissues by DNA hybridization techniques.³⁴ Viral DNA also can be detected in tissue samples by polymerase chain reaction (PCR); for example, in one fatal case of HHV-6 infection,⁴ DNA was extracted from postmortem liver and brain samples and amplified by the PCR test. Currently, HHV-6A and HHV-6B

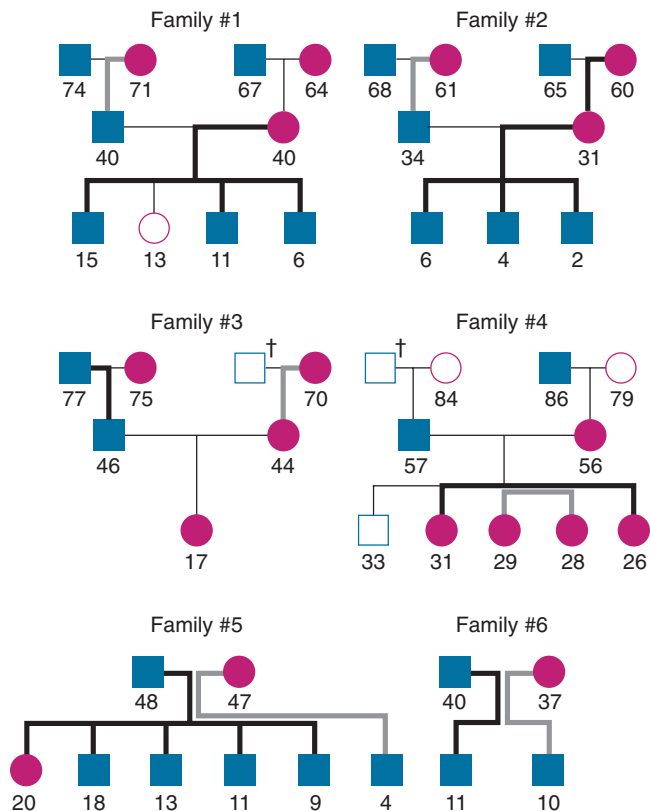

FIG. 161.2 Pedigrees of six families with human herpesvirus (HHV)-7 infection. All families resided in Okayama, Japan. Males and females are indicated as boxes and circles, respectively. Persons from whom HHV-7 was isolated are shaded. A person who was already deceased is marked (†). Members who have similar HHV-7 DNA restriction patterns are connected with bold lines. Numbers under the boxes and circles indicate ages. (From Takahashi Y, Yamada M, Nakamura J, et al. Transmission of human herpesvirus 7 through multigenerational families in the same household. *Pediatr Infect Dis J*. 1997;16:975-978.)

infections can be distinguished by PCR amplification technology.¹³ Extremely high copy numbers may indicate an integrated HHV-6 infection. Likewise, HHV-7 infection usually is diagnosed by PCR amplification of viral DNA in samples from patients.

Treatment of HHV-6 Infection

In most instances of HHV-6 infection in healthy children, treatment with an antiviral medication is not indicated. Recovery is complete within a few days after onset of the rash, and sequelae rarely occur. However, HHV-6 disease in immunocompromised children may be more persistent or severe (e.g., encephalitis). Several groups have analyzed the in vitro sensitivity of HHV-6 to four antiviral drugs: acyclovir, ganciclovir, phosphonoformic acid, and cidofovir.^{1,3} All four compounds have been used in treatment of other herpesvirus infections. Multiplication of HHV-6 in cell culture is inhibited readily by ganciclovir at a concentration of 2 to 10 µg/mL, levels that are easily achievable in humans. Phosphonoformic acid (foscarnet) at a concentration of 6 µg/mL also is effective against HHV-6 infection. On the other hand, HHV-6 is affected by acyclovir only at concentrations of 50 µg/mL, considerably higher levels than those required for treatment of HSV-1, HSV-2, and VZV infections and probably toxic in humans. Likewise, cidofovir has more side effects than ganciclovir and usually would not be recommended for HHV-6 treatment. At present, none of these antiviral drugs has been approved specifically for treatment of HHV-6 infections. One caveat for antiviral therapy for HHV-6 infection is the consideration whether the HHV-6 infection is related to chromosomally integrated HHV-6 DNA; these patients often have high copy numbers of HHV-6

DNA in the blood. Under these circumstances, however, antiviral therapy may exert no demonstrable effect.¹⁸

KAPOSI SARCOMA HERPESVIRUS (HUMAN HERPESVIRUS 8)

Yet another consequence of the HIV epidemic in the 1980s was the appearance of Kaposi sarcoma in many people with AIDS. The increase in Kaposi sarcoma was especially puzzling because the tumor occurred more frequently in people who acquired HIV by sexual transmission rather than by infusion of infected blood products, such as factor VIII in hemophiliac patients. The question often arose whether a second infectious agent was involved in the etiology of Kaposi sarcoma. The answer to that question was provided by a report published in late 1994. The authors announced the identification of a previously unknown herpesvirus-like DNA sequence collected from patients with AIDS in New York.⁹ The viral DNA was called *Kaposi sarcoma-associated herpesvirus* (KSHV). Other virologists prefer that the agent be called *human herpesvirus 8* (HHV-8).

Diseases Caused by Kaposi Sarcoma-Associated Herpesvirus

The authors of the original KSHV report were investigating patients with Kaposi sarcoma. They discovered the herpesvirus-like DNA sequences by using a combination of genetic techniques, including amplification of DNA by PCR and subsequent representational difference analysis.⁹ Thereby, they were able to identify and to characterize unique DNA sequences in Kaposi sarcoma that showed close homology to regions of the genome of *Herpesvirus saimiri*, a simian herpesvirus, and to a lesser degree to EBV, the agent that causes infectious mononucleosis. In their study, the authors located one or both of these herpesvirus-like DNA sequences in 20 of 27 different samples of Kaposi sarcoma tissue. The investigators correctly concluded that they had discovered DNA of a previously unknown herpesvirus within Kaposi sarcoma tissues.

Their virology results were confirmed quickly by other groups. In one study from California, investigators detected identical viral sequences in 13 of 13 biopsy specimens of Kaposi sarcoma from patients with AIDS.² This study also found the same sequence in the peripheral blood cells collected from 10 of the 13 patients but not in the blood samples of 20 patients with no history of Kaposi sarcoma. A third study from France found the herpesvirus-like DNA in biopsy specimens from five patients with Mediterranean-type Kaposi sarcoma; all five patients were HIV seronegative.¹¹ In subsequent studies, HHV-8 DNA has been detected in most Kaposi sarcomas (classic) in HIV-seronegative individuals, often men residing in the Mediterranean area.

The authors of the original KSHV report subsequently found the herpesvirus-like DNA sequences in body cavity-based lymphomas from patients with AIDS.⁸ HHV-8 DNA also has been found in the B-cell lymphoproliferative disorder known as *multicentric Castlemann disease*.⁵ Of equal importance, KSHV sequences were not found in several other lymphomas or leukemias (e.g., small-lymphocyte lymphoma, monocytoid B-cell lymphoma, follicular lymphoma, diffuse large-cell lymphoma, Burkitt lymphoma, lymphoblastic lymphoma, anaplastic large-cell lymphoma, multiple myeloma, hairy-cell leukemia, acute lymphoblastic leukemia, or cutaneous T-cell lymphoma). Recently, multicentric Castlemann disease has been diagnosed in an HHV-8 infected child, who may have had errors in innate immunity secondary to consanguineous parents.¹⁹

Transmission of HHV-8 Among Children

One of the most perplexing aspects of HHV-8 epidemiology is the mode of transmission. That the seroprevalence is high among a population of adult men who have sex with men is well known.²³ Yet, the question remains whether larger segments of the population are infected on a worldwide basis and, in particular, whether children are infected. To answer this question, several HHV-8 seroepidemiology studies were surveyed. Two studies provide partial answers to the question of childhood infection.

An early study was performed in a village in French Guiana, South America, among 1337 individuals of African origin.²⁴ They ranged in

age from 2 to 91 years. The serologic data indicated that HHV-8 seropositivity was strongly age dependent. Among 14 children aged 2 to 14 years, 3 of 146 were positive; aged 5 to 9 years, 14 of 278 were positive; aged 10 to 14 years, 31 of 232 were positive; aged 15 to 19 years, 24 of 149 were positive; aged 20 to 29 years, 38 of 236 were positive; aged 30 to 39 years, 16 of 120 were positive; aged 40 to 49 years, 19 of 70 were positive; and older than 50 years, 32 of 106 were positive. These seroprevalence data clearly show a gradual acquisition of infection during early childhood, with a stepwise increment from approximately 5% to 12% at age 10 years.

HIV infection did not play a role in the likelihood of transmission because HIV infection is not a common occurrence in this village. Instead, extensive analyses of intrafamilial relationships demonstrated a highly significant familial correlation in HHV-8 seropositivity between mother and child (especially when children were <10 years) and between siblings. The correlation was highest when the siblings had an age difference of less than 5 years. Of interest, a similarity in transmission appears to exist between HHV-8 and HHV-7, when HHV-7 was studied in multigenerational Japanese households (see Fig. 161.2).

A second large HHV-8 seroepidemiology analysis was performed in Israel.¹⁰ Because the incidence of classic Kaposi sarcoma in Israel is among the highest in the developed world, the investigators undertook a study to ascertain the HHV-8 seroprevalence in Israel and also to investigate HHV-8 intrafamilial transmission. The Israeli data showed that 9% of children aged 2 to 14 years and 9% of adolescents and young adults aged 15 to 24 years were HHV-8 seropositive. Seroprevalence in older adults ranged from 12% to 18%. HHV-8 positivity was more likely to occur in children when at least one of the parents was positive compared with children with neither parent positive. The most important predictor of a child's HHV-8 seropositivity status was maternal seropositivity.

HHV-8 seropositivity rises throughout adolescence and adulthood, regardless of HIV infection status.³³ In a recent review of KSHV infection in endemic countries, the authors reiterated that KSHV infection was spread among children primarily by exchange of saliva.²¹ Feeding young children food premasticated by the mother may be a particularly effective means of transmission. In contrast to CMV infection, KSHV infection is not spread via breastfeeding.²¹ In nonendemic countries in North America and western Europe, the seropositivity rate among HIV-seronegative adults is considered to be low, approximately 3% to 5%. The reasons for these differences between continents are not completely resolved. Nonetheless, a reasonable hypothesis is a decreased likelihood for transmission within smaller family groups in developed countries.¹² An alternative mode of infection, described next, is transmission by blood transfusion.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is a rare and sometimes fatal disorder of immune regulation, often associated with mutations in the perforin gene. Even carriers of the mutated gene may require an acute infection to trigger HLH. HHV-8 is one of the triggers. HLH in association with HHV-8 infection has occurred in adults with severe HIV infection or with a recent kidney transplant.^{13,19}

HLH has been diagnosed in two identical siblings from Iowa during the first 6 months of life.¹⁵ The siblings were born prematurely and spent several months in intensive care. Both siblings had mutations in the perforin gene. Both siblings had HHV-8 infection. Because the mother of the two was negative for HHV-8 infection, one possible route of transmission was a blood transfusion given while they were in the nursery. In fact, in a large study in East Africa, blood transfusions were shown to transmit HHV-8 infection.¹⁸ Therefore, children who have had multiple blood transfusions may be at risk for acquiring HHV-8 infection.¹¹

Diagnosis and Treatment of HHV-8 Infection

Diagnosis of prior HHV-8 infection can be made by serology. More commonly, diagnosis of acute HHV-8 infection can be accomplished by PCR amplification of HHV-8-specific DNA.^{9,11,12}

Treatment is not necessary in most healthy hosts because the virus quickly enters latency after the primary infection. No disease has been

associated with a latent infection in children, except in those with immunodeficiency. However, acute HHV-8 infection in recent transplant recipients or HIV-seropositive children could be an indication for treatment.^{13,19} Some of the same antiviral drugs described for HHV-6 treatment also inhibit HHV-8 replication (e.g., ganciclovir), but currently there are too few clinical data on which to base a standard regimen, so treatment would need to be individualized for each infected patient. Finally, for children coinfecting with HIV and KSHV, the use of highly active antiretroviral therapy (HAART) has curtailed HIV infection and thereby caused a sharp decline in the incidence of AIDS-defining syndromes such as Kaposi sarcoma.

Varicella-Zoster Virus

Anne A. Gershon

Varicella-zoster virus (VZV) causes two diseases: varicella (chickenpox) and zoster (shingles). Varicella, the primary infection, usually occurs in childhood and manifests as a pruritic rash accompanied by fever and other systemic signs and symptoms that usually are mild to moderate. Zoster is primarily a disease of adults, although it can occur in children. It develops when latent VZV, acquired with varicella or at vaccination, reactivates in a setting of low cell-mediated immunity to VZV as a result of disease or the use of various therapies, such as corticosteroids, cancer chemotherapy, organ transplantation, and irradiation. During primary infection, VZV establishes latency in sensory or other ganglia; zoster results when latent VZV reactivates in the neurons of the ganglia. Usually, reactivation results in skin infection and produces a unilateral dermatomal eruption that may be painful or pruritic. On occasion, however, VZV reactivation occurs without producing a rash; symptoms other than rash (such as aseptic meningitis) are the result of reactivation of VZV. Reactivation may also occur in the absence of symptoms.

The origin of the name “chickenpox” is uncertain, but it may have come from the French *pois chiche* (chickpea) or from the domestic fowl (in Old English, *cicen*, and in Middle High German, *kuchen*).⁵³ *Herpes* is the Greek word meaning “to creep,” and *zoster* comes from the Greek and Latin word meaning “girdle” or “belt.” Originally VZV was thought to be a poxvirus.

THE ORGANISM

VZV is an alpha herpesvirus. It has a DNA core surrounded by a nucleocapsid composed of 162 hexagonal capsomers that form an icosahedron with a diameter of approximately 100 nm. A tegument surrounds this structure, which in turn is surrounded by a lipid-containing envelope. Enveloped virions have a diameter of approximately 200 nm.⁶³ The genome of VZV has been sequenced; it contains 71 open-reading frames (ORFs).⁶⁵ The linear, double-stranded DNA consists of a long unique segment, U_L, and a short unique sequence, U_S, flanked by internal and terminal repeats.^{67,70,228} The genome of the Oka vaccine strain (vOka) also has been sequenced; the molecular basis for attenuation of the strain is still under investigation.^{4,107,158,251}

At least six genes of VZV—4, 21, 29, 62, 63, and 66—have been described as being expressed in human ganglia during latent VZV infection. VZV is synthesized by an orderly cascade of gene expression consisting of immediate-early (IE), early (E), and, finally, late (L) lytic genes that encode structural proteins. In *latent* infection there is thought to be a block in the cascade that permits synthesis of only roughly one tenth of the genes that are synthesized in productive or *lytic* infection. The genes expressed during latent infection are IE and E genes; L genes are not expressed. One hypothesis concerning latency is that cellular

immunity to VZV normally can control early replication of the virus so that productive or lytic infection does not occur.^{49,58-60,120,135-137,165,166}

During productive or lytic infection, VZV synthesizes more than 30 polypeptides; the function of most of these polypeptides remains unknown, but some are structural and others are nonstructural and presumably have regulatory action. VZV synthesizes at least nine glycoproteins (g): gB, gC, gE, gH, gI, gK, gL, gM, and gN.^{57,64,111,140} These glycoproteins correspond somewhat to those of herpes simplex virus (HSV), but, unlike HSV, VZV has no equivalent of gD, which is the major glycoprotein of HSV, nor of gG. The major glycoprotein of VZV is gE; it is the most abundant and immunogenic glycoprotein of VZV. The VZV glycoproteins not only provide structures for the virion but also play roles in infectivity, such as mediating adhesion and promoting entry of VZV from an infected cell into another uninfected cell. The glycoproteins also are antigenic, as is the tegument, and immune responses are directed toward these structures.

Just one antigenic type of VZV has been identified. Three major classifications of wild-type (WT) VZV were originally described, referred to as European (E), Japanese (J, for strains homologous to the Oka parental vaccine strain), and Mosaic (M, for strains displaying a combination of European and Japanese genotype-like mutations).^{19,163,213,238} Worldwide, six VZV clades have now been described, with three additional putative clades. The clades have differing geographic origins, which have been influenced by worldwide immigration patterns. All six clades have been observed in the United States, although clades 1 and 3 (both E) predominate.²⁹ vOka is derived from a clade 2 strain, which is mainly found in Asia.

Wild-type VZV DNA can be distinguished from that of vaccine-type (Oka) virus by restriction enzyme analysis of DNA from cultured virus and/or by polymerase chain reaction (PCR) assay and by direct sequencing, particularly of three gene segments at positions 106262, 107252, and 108111 in ORF 62, which contain the major mutations in Oka.^{4,107,148,162,171,181,198,210}

VZV replicates in the nuclei of infected cells, where the DNA core and capsid are synthesized. The capsid is enveloped by a complex process in the Golgi apparatus, after which it traverses the cell in cytoplasmic vesicles.⁹⁴ In vitro, and in patients with VZV infections, the virus grows rather slowly and is highly cell associated. Its synthetic pathway entraps it in endosomal vesicles, where it is inactivated before it can be released from cells in infectious form. In vivo, however, infectious VZV is released from cells of the superficial epidermis and is highly contagious; this may be the only place in the body where cell free virus is produced. VZV avoids the endosomal route in this particular tissue because of the loss of its receptor (the large calcium-independent mannose-6-phosphate receptor) and thereby it can exit epidermal cells in infectious form by the secretory pathway.⁵⁰

VZV has an extremely limited host range and infects mostly primates. Various strains of guinea pigs, including hairless ones, may be infected with VZV, but either no symptoms are produced or the illness produced is extremely mild, although specific immune responses can be demonstrated.¹⁸² Animal models of latent VZV infection have been described in rodents, including guinea pigs.^{48,177,204,250} An *in vitro* model of latency and reactivation of VZV in intestinal neurons from guinea pigs has recently been developed.⁴⁹

TRANSMISSION

VZV is spread by the airborne route¹⁵⁰ and requires contact with an infected individual for transmission to occur. In varicella, VZV is transmitted mainly from the skin^{50,233}; the respiratory tract cannot be excluded but is not likely to be a significant mode of viral spread. VZV is isolated readily from skin lesions, but isolation of the virus from the respiratory tract just before or during rash is extremely rare.^{106,187,231} Spread of VZV from varicella patients before the onset of rash in closed communities has been reported, implicating respiratory spread, although early skin lesions could have been overlooked.^{31,108} VZV DNA has been detected by PCR assay in the nasopharynx of children during the preeruptive and early stages of varicella.^{138,188,208} Investigations of leukemic recipients of live attenuated varicella vaccine have implicated spread of VZV from skin. No transmission to siblings from vaccinees who did not have a rash was found, but a 14% transmission rate occurred when siblings were exposed to a recently immunized child who had a vaccine-associated rash.²³³ The chance of transmission occurring was directly proportional to the number of skin lesions present.²³³ Observations in children with WT varicella despite their having been immunized indicated that higher transmission rates are associated with greater numbers of skin lesions.²¹⁵ Interestingly, an attack rate of more than 20% occurred after medical students were exposed to VZV during the autopsy of a patient with disseminated varicella; clearly, this transmission could not have occurred by the respiratory route.¹⁹⁰ Taken together, these observations suggest that VZV spreads mainly from skin lesions rather than from the respiratory tract. Epidemiologic studies suggest that transmission is most likely to take place in the early stages of varicella.^{39,180}

Zoster is not transmissible *per se*, but the vesicular lesions of zoster contain infectious VZV and can transmit varicella to other individuals who have not yet had primary infection.^{32,144} Zoster is perhaps 75% less contagious than is varicella,^{201,212} and whether VZV is spread from the respiratory tracts of patients with zoster is unknown. Presumably, however, the major source of contagion, as for varicella, is the skin lesions.²¹²

EPIDEMIOLOGY

VZV infections occur worldwide, and both sexes are affected equally. The virus spreads less efficiently in countries with tropical climates than in those with temperate climates,¹²⁴ thereby resulting in a high rate of susceptibility in adults reared in tropical countries. In the pre-vaccine era, approximately 3.8 million cases of chickenpox, an entire birth cohort, occurred annually in the United States. At that time, 8% to 9% of children between the ages of 1 and 9 years contracted the illness annually.¹⁹⁵ These data were collected before many children attended daycare facilities; exposure to VZV in the daycare setting might have led to earlier acquisition of disease. Today there is little varicella disease in the United States owing to widespread routine vaccination. (See the later discussion of the health effects of widespread immunization in the United States.)

The link between varicella and zoster was recognized first about 100 years ago when Bokay²⁷ appreciated that cases of varicella often occurred after exposure to a patient with zoster. Early in the 20th century, medical investigators inoculated vesicular fluid from zoster patients into varicella-susceptible children, who then contracted chickenpox.^{32,144} Weller first successfully isolated VZV *in vitro*, gave the virus its name, and demonstrated that the viruses isolated from patients with varicella and zoster are identical.²⁴³ Garland proposed that zoster is the result of reactivation of latent VZV.⁸¹ Hope-Simpson presciently recognized the importance of the immune system in preventing reactivation of VZV;

he postulated that periodic exposure to varicella (external boosting) and asymptomatic reactivation from latency (internal boosting) stimulate immunity to VZV and that zoster results when despite these boosts, immunity to VZV wanes as the immune system begins to deteriorate during aging.¹²³ Declining cell-mediated immunity to VZV has been identified as contributing significantly to the development of zoster.^{9,21,34,118} With the use of molecular techniques for DNA analysis, researchers have established that the DNA of the viruses causing varicella and zoster is the same, and autopsies and surgical specimens have revealed that latent VZV is detectable in neurons of the sensory ganglia of individuals with a past history of varicella or vaccination.^{61,86,136,164,167} Zoster is not acquired by contact with patients who have zoster or chickenpox, but by reactivation of latent VZV.³⁰ Zoster is said to develop in approximately 30% of the varicella-immune population during their lifetimes, resulting in an annual rate of 1 million cases, but the true incidence of zoster is probably underestimated due to a significant number of cases with very mild, nonexistent, and/or atypical rashes.¹⁸⁶

Varicella is highly contagious; clinical infection develops in 80% to 90% of susceptible individuals exposed in a household.²⁰² Secondary varicella cases in a family usually are more severe than primary cases, probably because of intensity of exposure.^{194,202} Approximately 75% of American adults with no past history of varicella have detectable antibodies to VZV,¹⁴⁹ thus indicating that subclinical varicella can occur. One epidemiologic study suggests that its incidence is approximately 5%.²⁰²

Subclinical zoster also may occur, and zoster with dermatomal pain and no rash has been described (zoster sine herpette).¹⁰¹ Increases in VZV immune responses and episodes of viremia shown by PCR assay in asymptomatic individuals indicate that silent reactivation occurs.^{97,112,248} Asymptomatic shedding of infectious VZV is essentially nonexistent.

Second attacks of varicella are uncommon but may happen more frequently in persons who are immunocompromised than in immunologically normal individuals.^{98,131} Immunologic boosting to VZV occurs commonly on reexposure to the virus.^{8,91,98} Whether exogenous boosting is necessary for long-term maintenance of immunity to VZV is not known for certain. A recent study suggests that exogenous boosting is unlikely to be required, probably because of the phenomenon of internal boosting. The long-term incidence (over a 30-year period) of herpes zoster was found to be similar in isolated communities of people (monks and nuns) compared to individuals living in the general public.^{62,78}

Adults and children older than age 2 years with zoster usually have a history of a previous attack of varicella or vaccination.^{123,217} Zoster may be due to vaccine type or WT VZV. In vaccinated children with zoster, approximately half of cases are caused by WT VZV.^{46,47,79,217,242} Zoster caused by vOka appears to be no less severe than that caused by WT VZV. Zoster is an unusual event in children, but the incidence is increased in young children who had varicella either *in utero* or before reaching their second birthday.⁶⁹ Chickenpox in the first year of life increases the risk for development of childhood zoster by a relative factor between roughly 3 and 21,¹¹³ possibly because of immaturity of the immune response to VZV in young infants. Infants with the congenital varicella syndrome are at greatly increased risk, as high as 18% in the first few years of life, for the development of zoster.⁸⁵ In vaccinated children aged 3 to 9 years old, the reported incidence of zoster is 0.39 per 1000 person-years of observation. In children of a similar age with a history of natural varicella the incidence is higher, 1.39 per 1000 person-years. In young vaccinated children the incidence of zoster was reported to be higher than in children of a similar age who were not vaccinated, but this is not a fair comparison because unvaccinated children less than 3 to 4 years old are unlikely to have had varicella and therefore are not at risk to develop zoster. Actually the incidence of zoster is likely to be even lower in vaccinees than after natural infection because of the high incidence of wild-type zoster (50%) in vaccinees who were given only one dose of varicella vaccine. With time, better information on the true incidence of zoster caused by vaccine-type VZV should become available in individuals after the recommended two doses of varicella vaccine.

The incidence of zoster in a population begins to increase sharply at approximately 50 years of age.¹²³ In healthy young adults the incidence of zoster is roughly two cases per 1000 person-years of observation.

This increases by a factor of 3 to 5 as a population ages. The loss of cell-mediated immunity to VZV that occurs naturally with normal aging contributes to the increased incidence of zoster, as does aging of the population, increases in immunocompromised individuals due to disease and various medications, stress, and other factors.^{21,34} A computer modeling study in 2002, of long-term immunity to zoster in young adults in the vaccine era when exposure to wild-type VZV would be decreased, predicted a doubling of the incidence of zoster with significant morbidity.³⁰ Fortunately evidence collected in the past 13 years has failed to support this hypothesis.¹¹⁶

It is now clear that zoster can be prevented by therapeutic immunization of varicella immunes. In a double-blind, placebo-controlled study involving more than 38,000 healthy individuals older than 60 years, immunization with a live attenuated zoster vaccine (Oka strain) reduced the burden of illness of zoster by 61%.¹⁸⁶ Zoster vaccine in the United States contains approximately 20,000 plaque-forming units of VZV, and it is approximately 14 times as potent as monovalent varicella vaccine.¹⁸⁶ Recently, the efficacy and safety of this vaccine in persons between ages 50 and 59 years was demonstrated, although this vaccine is not routinely recommended for healthy persons younger than the age of 60 years.²⁰⁹ Recent studies of vaccination of healthy older individuals with an adjuvanted (noninfectious) subunit zoster vaccine based on gE of VZV indicated over 90% efficacy of prevention of zoster over a 3-year period.¹⁴⁷ This vaccine has not yet received FDA approval, but when that occurs, it is likely significantly to improve patient care with regard to vaccination against zoster of healthy and immunocompromised individuals.

Zoster also develops with increased frequency in patients with neoplasms and organ transplants¹⁶¹; in severely immunocompromised patients with zoster, disseminated infection with viremia also may occur.⁷⁴ Spinal trauma, irradiation, diabetes, and corticosteroid therapy may be additional precipitating factors. Children who are infected with human immunodeficiency virus (HIV) and have CD4⁺ levels less than 15% when varicella develops are at great risk for the development of zoster; in one published series, the incidence of herpes zoster was 70%.⁹² HIV-infected children who have received varicella vaccine with relatively normal CD4 cell records, however, rarely experience zoster.²²¹

Zoster may develop in healthy children or young adults who are not immunocompromised, presumably the result of a transient fall in cell-mediated immunity to VZV caused by a stimulus such as another viral infection or stress. Zoster does not develop in all immunocompromised persons; the deficiency of cell-mediated immunity to VZV is a necessary but not sufficient requirement for this illness to develop. The distribution of lesions in chickenpox, which primarily involves the trunk and head, is reflected in a proportionately greater representation of these regions in the dermatomal lesions of zoster.²²⁶ Zoster may recur in either the same or a different dermatome; the chance of developing recurrent zoster is similar to the chance of having a first attack for a particular age group and is reported as occurring in 2% to 5% of adults, but this may be an underestimate.^{123,199}

Varicella occurs most commonly in the winter and early spring. In contrast, zoster occurs at equal rates during all seasons of the year. VZV may seed ganglia and establish neuronal latency either directly from skin lesions or by viremia.⁴⁸

PATHOGENESIS

The incubation period of varicella ranges from 10 to 23 days (average, 14 days).¹⁰⁸ VZV can be isolated from blood cultures either a few days before the onset of rash or within 1 to 2 days after onset in immunocompetent children.¹¹ VZV reaches tonsillar keratinocytes soon after infection and infects CD4⁺ memory T cells that normally circulate through the skin. Overcoming innate immunity in skin accounts for the 2- to 3-week incubation period that follows infection.^{142,143}

The skin lesions of VZV infection begin as macules and progress rapidly to papules, vesicles, pustules, and scabs. Histologic changes in the skin lesions are similar for chickenpox and zoster. The hallmarks of each disease are multinucleated giant cells and intranuclear inclusions. In varicella, they are localized primarily in the dermis and epidermis, where ballooning degeneration of cells in the deeper layers is accompanied

by intercellular edema. As the edema progresses, the cornified layers and basal layers separate to form a thin-roofed vesicle. An exudate of mononuclear cells is seen in the dermis.^{2,243} In zoster, in addition to skin lesions that resemble those of varicella, a mononuclear inflammatory infiltrate is present in the ganglion of the affected dermatome. Hemorrhagic necrosis of ganglion cells and demyelination of the corresponding axon also may be present.^{72,121,164}

Both humoral and cell-mediated immune responses to VZV develop within a few days after the onset of varicella. Peak antibody levels are attained 4 to 8 weeks after onset, remain high for approximately 6 months, and then decline. IgG VZV antibody titers are detectable in healthy adults for decades after recovery from varicella.^{96,225,247} After active immunization against varicella, antibody titers are lower than after natural infection occurs but persist for as long as 20 years in healthy vaccinees immunized as children.²⁴⁴ Serum IgG, IgA, and IgM are detectable after both varicella and zoster. Zoster occurs despite high levels of specific antibodies, but significantly higher titers develop during convalescence and are indicative of an anamnestic response to VZV in this secondary infection.²³⁵

Cell-mediated immune responses (adaptive immunity) are thought to play the major role in host defense against VZV. Cell-mediated immunity to VZV can be demonstrated *in vitro* by stimulation of lymphocytes with VZV antigens,^{118,252} an intradermal skin test,¹⁴⁹ specific lysis of histocompatible target cells by cytotoxic T cells,⁶ and an enzyme-linked immunosorbent spot assay.¹⁵⁶ The predominant cell in VZV vesicular lesions is the polymorphonuclear leukocyte. These leukocytes play a role in generating interferon in vesicular lesions, which may be a factor in recovery.²²⁷ Natural killer (NK) cells are also important in host defense (innate immunity) against VZV and other herpesviruses.¹²⁶ The importance of NK cells in immune responses to VZV was discovered in children who developed severe wild-type varicella or serious reactions to varicella vaccine who lacked NK cells.^{18,24,73,157,185}

Individuals with past varicella may experience boosts in VZV immunity in the absence of symptoms or exposure to the virus, suggesting subclinical reactivation of VZV, which may be important in preserving long-term immunity to the virus.^{160,211,248} Cell-mediated immune reactions remain positive for years after varicella, although this response wanes in many individuals older than 50 years.^{21,34}

Exactly how immunity to varicella and zoster is mediated is unclear and also complex. Because patients with isolated agammaglobulinemia do not experience either severe or recurrent varicella, researchers long presumed that cell-mediated immunity is more important in host defense than humoral immunity; we now recognize that T-cell cytotoxicity is crucial in recovery from VZV infection and that NK cells also play a part.^{7,18,24,73,157,185} The response or responses that prevent clinical illness after reinfection with VZV are presumed to be those of cytotoxic T lymphocytes, but antibodies also may play a role. Elderly individuals with poor cell-mediated immune responses to VZV are not subject to recurrent chickenpox. In addition, specific antibodies must have some importance because passive immunization is used successfully to prevent or to modify varicella in exposed susceptible persons, perhaps by neutralization of cell-free VZV early in the infection. These issues, however, are not straightforward. Varicella may develop in young infants after exposure despite detectable transplacental antibody titers,¹⁴ and modified cases of breakthrough varicella have developed in vaccinated leukemic children despite the presence of humoral or cell-mediated immune responses at exposure to VZV.^{95,99} Still, clinical illness is far less likely to develop in individuals with detectable antibody titers or positive cell-mediated immune responses (or both) at exposure to VZV than in those without positive immune responses. Possibly, some forms of cell-mediated immunity and specific antibodies each play roles in host defense against VZV, and there may be some redundancy in the system.

NOSOCOMIAL VARICELLA

Although it is probably less of a problem since licensure of varicella vaccine, nosocomial varicella is a potentially serious and expensive problem in hospitals, where both patients and employees may be susceptible to chickenpox.^{110,115,240} Because varicella-susceptible hospital

employees may serve as vectors for the spread of VZV to susceptible patients, serologic testing of employees for immunity to chickenpox with no past history of having clinical varicella and offering vaccine to those who are susceptible are standard measures in many hospitals. The results of serologic tests for varicella are often unreliable, however, so another approach is to administer two doses of vaccine at least 1 month apart to health care workers with no history of previous varicella or zoster and not to perform serologic testing. Inadvertent vaccination of immune individuals is not harmful.

The risk for horizontal transmission in maternity wards or the neonatal nursery after hospital exposure to an adult or child is surprisingly low.⁸⁵ A few episodes of nursery transmission of varicella have been reported,^{77,93,114} but the low incidence of such transmission may be, at least partly, because many infants are in isolettes. Furthermore, most hospital employees and most mothers and their neonates have antibodies to VZV and are at low risk for the development of clinical illness. Even in low-birth-weight infants, antibodies to VZV may be detectable.^{176,200}

CLINICAL MANIFESTATIONS

Varicella

Varicella is a highly contagious, usually self-limited systemic infection characterized by fever and a generalized pruritic rash lasting approximately 5 days. A prodromal phase in children is unusual, but malaise and fever for 1 to 2 days before the onset of rash is a common manifestation in adults.⁵³ The rash is more intense on the trunk and head than on the extremities, and it typically evolves as a series of “crops” during the course of 1 to 3 days in normal hosts. Most children with varicella have 250 to 500 superficial skin lesions, many of which are vesicular (Fig. 162.1).²⁰² Not uncommonly, a few lesions may develop in the mouth, conjunctiva, or other mucosal sites. Residual scarring is exceptional but can occur, and depigmented areas of skin may develop in dark-skinned patients. A self-limited increase in hepatic transaminase levels without jaundice is not an uncommon occurrence during varicella.¹⁹³ Rarely, thrombocytopenia and neutropenia may transiently occur. Severe infections are more likely to develop in adults than in children, presumably because of less robust cell-mediated immune responses to VZV in adults than in children.^{82,183} Neonates who acquire varicella from their mothers in the few days before delivery also are at risk for acquisition of severe varicella because of immaturity of the cell-mediated immune response.⁸⁵

Complications of Varicella

The most frequent complications of varicella in normal hosts are bacterial superinfections and central nervous system (CNS) complications. Bacterial superinfection usually involves the skin, lungs, or bones; these are most often caused by *Staphylococcus aureus* or group A β -hemolytic streptococci.^{28,249} CNS complications, which may precede or follow varicella, include transient cerebellar ataxia, severe cerebral encephalitis, aseptic meningitis, and transverse myelitis.^{129,130} Recently it was found that the incidence of stroke in children is increased in the months

following varicella.⁵⁴ An exhaustive study did not find an association of increased stroke incidence in children who were vaccinated against varicella.⁶⁶ Encephalopathy as a sequela of Reye syndrome has become a rare complication because aspirin no longer is recommended for children with varicella. Other complications of chickenpox encountered less commonly include arthritis, glomerulonephritis, myocarditis, and purpura fulminans.²⁴³

Varicella may be severe and even fatal in immunocompromised patients, including those with an underlying malignant neoplasm or congenital or acquired deficits in cell-mediated immunity, such as patients who have undergone organ transplantation or have underlying HIV infection, and in children receiving high doses of corticosteroids for any reason (Fig. 162.2).⁷⁶ These patients may be susceptible to progressive varicella, with continuing fever and the development of new vesicular lesions for 2 weeks or longer. Their skin lesions characteristically are large, umbilicated, and hemorrhagic, and primary varicella pneumonia is a frequent complication. Often children with severe varicella will present with severe abdominal pain.¹⁷³ This is not surprising because VZV may invade the gastric mucosa.¹⁵ Alternatively, in some immunocompromised patients, an acute form of varicella with disseminated intravascular coagulation develops and is rapidly fatal, at times before antiviral therapy can be instituted. A 30% rate of dissemination with a 7% fatality rate was reported in leukemic children in whom chickenpox developed in the pre-antiviral drug era.⁷⁵ Severe varicella has been observed in children with underlying HIV infection, especially those classified as having acquired immunodeficiency syndrome (AIDS).¹³² In most HIV-infected children, however, mild to moderate forms of varicella develop, although the illness generally is more severe than that in otherwise healthy children.⁹² Varicella does not seem to be a cofactor for clinical progression of HIV infection to AIDS, but in approximately 5% of these children, chronic wartlike hyperkeratotic VZV lesions may develop after varicella, presumably being a chronic form of zoster in which the infection is low grade but persistent.⁵

Primary varicella pneumonia accounts for many of the fatalities ascribed to varicella, particularly in immunocompromised patients and adults.¹⁹¹ In male military recruits with varicella, radiographic evidence of pneumonia was found in 16%.²⁴¹ Symptoms include fever, cough, and dyspnea. Other common symptoms and signs are cyanosis, rales, hemoptysis, and chest pain. The chest radiograph typically reveals a diffuse nodular or miliary pattern that is most pronounced in the perihilar region.²³⁰ Blood gas analyses and pulmonary function tests indicate a diffusion defect that may persist in some cases for months after recovery.²⁶ The availability of antiviral chemotherapy has greatly improved the outcome of this complication.

FIG. 162.2 Progressive varicella in a 9-year-old child with underlying leukemia.

Congenital Varicella Syndrome

LaForet and Lynch, who were medical students in 1947, were the first to describe an infant with multiple congenital anomalies after contraction of maternal chickenpox.¹⁴⁶ The infant had hypoplasia of the right lower extremity, clubfoot, and absent right deep tendon reflexes, along with cerebral cortical atrophy, cerebellar aplasia, chorioretinitis, torticollis, insufficiency of the anal and vesical sphincters, and cicatricial cutaneous lesions on the left lower extremity. These manifestations are now recognized to be typical of this syndrome. In 1974, Srabstein and colleagues rediscovered this syndrome, which appeared to have been forgotten.²²³ Their report of another case and review of the literature concluded that although the virus could not be isolated from affected infants as with congenital rubella or cytomegalovirus infection, the congenital syndrome consisted of a typical constellation of birth defects as originally described by LaForet and Lynch. This syndrome occurs after maternal VZV infection develops in the first or second trimester of pregnancy; approximately 2% of the offspring of pregnancies complicated by varicella are affected. Approximately 100 affected infants have been described in the literature; 95% occurred after maternal varicella and 5% after maternal zoster. In the pre-vaccine era, approximately 40 affected infants were thought to be born annually in the United States.⁸⁵ Today in the vaccine era, this syndrome may once more be forgotten.

Cicatricial scars of the skin, the most prominent stigmata, are reported in more than 60% of cases.⁸⁵ Other frequent abnormalities include chorioretinitis, microphthalmos, Horner syndrome, cataract, nystagmus, hypoplastic limbs, cortical atrophy or intellectual disability (or both), and early death. Many of these children develop zoster (in which VZV can be identified) in the early months of life. There is a high correlation between limb abnormalities and a poor outcome in these infants. The Oka strain is not known to cause the congenital syndrome.⁸⁵

Zoster

Zoster usually begins as a localized unilateral vesicular skin eruption involving one to three dermatomal segments (Fig. 162.3). The skin lesions resemble those of varicella but tend more toward confluence and are likely to be painful or pruritic, especially in adults. Zoster generally is a milder disease in children than in adults. Zoster may follow natural varicella or vaccination; however, the incidence of zoster is clearly lower after vaccination than after varicella disease, even in immunocompromised vaccinees.^{117,118,232}

FIG. 162.3 Zoster in an otherwise healthy 10-year-old boy.

Zoster is a considerable cause of morbidity, but death is unusual or rare.¹⁶⁸

Complications of Zoster

Two kinds of pain are associated with herpes zoster: (1) acute pain that is related to reactivation of VZV in sensory neurons and (2) pain that develops after the acute phase of the illness, often in the area of healed rash. Between 25% and 50% of persons older than 50 years in whom zoster develops may experience late protracted pain, or postherpetic neuralgia, after the rash has healed. Postherpetic neuralgia (PHN) also occurs frequently in immunocompromised patients. Pain may persist for months to years and is described as aching, jabbing, or boring. The cause of PHN is unknown but may be related to healing of injured nerves. Otherwise healthy children rarely experience PHN; both the incidence and duration are related directly to increasing age.^{102,103} Zoster may be particularly severe and common after bone marrow transplantation; in the first year after undergoing transplantation, 20% to 70% of recipients develop zoster.⁸³

Neurologic complications of zoster in addition to PHN include meningitis, stroke, and various forms of paralysis. Meningitis can present either with or without the presence of a zosteriform rash. It can occur in immunologically normal individuals, in whom the prognosis is good, and in immunocompromised persons, in whom the prognosis can be problematic. The diagnosis is made by demonstration of VZV DNA in cerebrospinal fluid (CSF); it is quite rare to culture VZV from CSF.¹²⁸ Stroke is more common after zoster than after varicella. Strokes after zoster are more often seen in adults than children, possibly because zoster is more common in adults than in children, as well as other factors. Strokes that follow zoster are due to vasculopathy and ischemia; VZV particles have been demonstrated in cerebral arteries in strokes associated with zoster, indicating viral replication. Whether treatment with antivirals improves the prognosis of this form of stroke is unknown at present. Other neurologic complications of zoster include various forms of paralysis, retinal necrosis, and giant cell arteritis; in addition to demonstrating VZV DNA in CSF, the diagnosis may be made by the presence of VZV antibodies in CSF.^{104,105,172} Immunodeficiency diseases have been unmasked on rare occasions in patients with severe VZV neurologic complications involving vaccine-type VZV following varicella immunization.²⁰³

Visceral zoster, involving the gastrointestinal tract, may produce severe abdominal symptomatology, at times in the absence of rash; this is ascribed to latent VZV in enteric ganglia with reactivation and local spread of the infection.^{48,86,71} If there is no rash, the diagnosis is made much more difficult. Zoster may cause a wide variety of gastrointestinal disorders, including achalasia, gastric and duodenal ulcers, and colonic pseudoobstruction.^{71,87,179} At times the diagnosis is made when abdominal pain is the chief complaint and this is accompanied or followed by the typical rash of zoster. At other times the diagnosis is made when gastrointestinal tissue becomes available for study and VZV is demonstrated by molecular studies such as PCR and/or immunofluorescence. Testing saliva for VZV DNA has been used as a screening test for visceral zoster.⁸⁷

DIAGNOSIS

Clinical Diagnosis of Varicella and Zoster

It usually is not difficult to establish a clinical diagnosis of VZV infection because the vesicular rash is so characteristic. In questionable cases of varicella, epidemiologic information, such as a history of recent exposure to varicella or zoster and subsequent transmission of varicella to another person, may be useful. The differential diagnosis of varicella includes generalized HSV infection, enterovirus infections, rickettsialpox, impetigo, allergic reactions (including Stevens-Johnson syndrome and poison ivy), and insect bites.

Zoster rashes are unilateral and often painful or pruritic. There may be some scattered vesicles outside of the dermatome. Rashes of zoster and HSV can resemble each other. In one study of zoster, 13% of clinically diagnosed zoster cases were proven by culture to be caused by HSV infection.¹³³ The unilateral rash of zoster most frequently appears on the trunk or face. The trigeminal nerve, most commonly the ophthalmic

branch, is an especially significant site because the eye may be involved. When skin lesions are absent, diagnosis of zoster has to be made by laboratory testing.

Laboratory Diagnosis

Laboratory diagnosis of VZV infection is facilitated by the presence of VZV in superficial skin lesions, where it is easily accessible for testing. The diagnosis is made best by the demonstration of specific viral antigens or VZV DNA in skin vesicles or scrapings. VZV antigens are demonstrable by immunofluorescence with a commercial monoclonal antibody to VZV that is conjugated to fluorescein.⁸⁸ Immunofluorescence testing is highly sensitive and can be completed within approximately an hour. PCR assay is used to demonstrate VZV in skin lesions and also in saliva and CSF when there is CNS involvement with VZV.^{87,189} PCR is more sensitive than immunofluorescence and is becoming the preferred method for diagnosis of VZV.^{88,236} PCR also may be used to distinguish between vaccine (Oka strain) and wild-type VZV infections.^{88,198}

The diagnosis also may be made by isolation of virus from skin lesions very early in the course of illness. Within several days after the onset, vesicular fluid no longer is likely to be infectious, although viable VZV may be present in zoster lesions for a longer period compared to varicella, especially in immunocompromised patients. VZV cannot be isolated from skin lesions that have become pustular or dry. Isolation of VZV is a slow method because at least 48 hours is required before the first signs of a viral cytopathic effect are seen. It is also less sensitive than is immunofluorescence or PCR. VZV rarely is isolated from respiratory secretions or from infected CSF during VZV meningitis.¹⁰⁶ Demonstration of VZV DNA, antigens, or isolation of virus from samples obtained from skin, other sites, or autopsy tissue is diagnostic of a current infection with VZV because, unlike other herpesviruses, no known carrier state or shedding of VZV by asymptomatic individuals exists.⁸⁸ VZV infections can also be diagnosed by demonstration of viral DNA in saliva.^{87,154,174,175}

Numerous serologic tests, including the fluorescent antibody to membrane antigen (FAMA) method and enzyme-linked immunosorbent assay (ELISA), are useful for measuring antibodies to VZV.⁸⁸ Antibody to VZV develops within a few days after the onset of varicella, persists for many years, and is present before the onset of zoster. VZV infections may be documented by a fourfold or greater rise in VZV antibody titer in acute and convalescent serum specimens. Specific IgM in one serum specimen suggests recent VZV infection, either varicella or zoster; false-negative and false-positive reactions, however, are a problem with this assay. Persistence of VZV IgG antibody beyond 8 months of age in an infant is highly suggestive of intrauterine varicella.⁹³ Immunity to varicella is present if a positive FAMA titer to VZV is demonstrated on a single serum sample after varicella or immunization.¹⁷⁸ Serologic methods, however, particularly commercial ELISAs, may fail to identify individuals who have had natural infection or have been immunized.^{88,225} Unfortunately, the FAMA assay is not now readily available.

The value of serologic procedures for the diagnosis of zoster is limited. Heterologous increases in antibody titer against VZV in patients with HSV infection who previously had varicella may occur and have been ascribed to antigens common to the two viruses.⁸⁸ Laboratory diagnosis of zoster is best accomplished by PCR assay on skin lesions or in saliva.⁸⁷ As has been mentioned, it is possible to differentiate between Voka and WT VZV by molecular methods.

TREATMENT

Traditionally, nonspecific measures, such as frequent bathing to discourage bacterial skin infection, antihistamines given orally, calamine lotion applied locally, oatmeal baths to decrease itching, and cutting fingernails short to discourage scratching, have been used to treat varicella. Fever is controlled best with acetaminophen rather than aspirin, which may predispose to Reye syndrome.¹¹⁹ The issue of whether treatment with ibuprofen is associated with group A streptococcal superinfection in varicella has not been resolved, and, therefore, avoidance of its use for symptomatic treatment of varicella seems to be the best approach.^{35,52,152,254}

Useful specific antiviral therapy for VZV became available in the mid-1980s with the introduction of the nucleoside analogue acyclovir,

an inhibitor of DNA polymerase and a DNA chain terminator. The antiviral effect of acyclovir depends on its being phosphorylated in the body by virus-induced thymidine kinases, which accounts for its relative lack of toxicity.²⁴⁶ Antiviral therapy for varicella and zoster is similar.

Patients with severe or potentially severe VZV infections should be treated with intravenous acyclovir 30 mg/kg per day for adults and adolescents and 1500 mg/m² per day for children, both given in three divided doses. Orally administered acyclovir is less reliable for immunocompromised patients because only approximately 20% of this formulation is absorbed from the gastrointestinal tract, and no data on its efficacy in high-risk patients have been published. Because acyclovir is excreted by the kidneys, patients with a creatinine clearance of less than 50 mL/min per 1.73 m² should receive one-half to one-third of this dosage. Intravenous acyclovir is infused for at least 1 hour, with maintenance fluids given both before and during the infusion. Providing adequate hydration is important to prevent renal damage from precipitation of the drug in the renal tubules. Other adverse effects of acyclovir include phlebitis, rash, nausea, and neurologic manifestations such as headache and tremor. In general, however, acyclovir is extremely well tolerated.²⁴⁶

Early intravenous therapy should be instituted for patients at high risk for development of severe VZV infection, such as leukemic children and those who have undergone organ or bone marrow transplantation, to prevent the dissemination of VZV.^{218,245} Not only may this therapy be potentially lifesaving in immunocompromised patients, but it also prevents considerable morbidity from VZV infection. Children thought to be somewhat less immunocompromised, such as those with HIV infection but without AIDS, may be given a treatment trial with oral acyclovir under close medical supervision. In such patients who are not doing well, intravenous therapy should be administered. In zoster patients, the use of intravenous acyclovir is associated with more rapid healing of skin lesions and resolution of acute pain than if no specific treatment is given.²⁴⁶

Considerable controversy has ensued about the role of orally administered acyclovir for the treatment of varicella and zoster in otherwise healthy children because most of these infections are self-limited. Customarily, however, adults, who are at greater risk for development of severe infection, are treated. Oral dosages used are 80 mg/kg per day (in four divided doses) for children and 4 g/day (in five divided doses) for adults. Double-blind, placebo-controlled studies in healthy children given oral acyclovir at 80 mg/kg per day for 5 days or placebo beginning within 24 hours of the onset of varicella rash have revealed that the number of chickenpox skin lesions is reduced significantly by acyclovir. A modest benefit was derived from acyclovir; children who received it had fever for approximately 1 day less, but they did not return to school any more rapidly, nor did they have fewer complications of chickenpox.^{17,68}

Some evidence indicates that early administration of oral acyclovir may decrease the acute pain associated with zoster.¹²⁵ However, the need to administer specific therapy for zoster in otherwise healthy children for whom pain is not a particular problem rarely occurs. Usually however, children with zoster are treated in order to speed recovery.

The newer drug, penciclovir, has an action similar to that of acyclovir.¹²² It is administered as famciclovir, a prodrug that when given orally is converted rapidly to penciclovir in the body. A major advantage of famciclovir is that it is administered only three times a day (1500 mg/day for an adult), whereas acyclovir is given four or five times daily. Penciclovir has an antiviral action similar to that of acyclovir. One study suggests that famciclovir given to elderly patients with zoster early in the course of infection decreases the duration of PHN, although not its incidence.²³⁴ No data regarding whether varicella may be treated successfully with famciclovir have been published, nor have any data on the use of famciclovir in immunocompromised patients or in children.

The prodrug of acyclovir, valacyclovir, also is given orally, reaches blood levels that are approximately three to four times higher than those following oral acyclovir and has been shown in one study to be superior to acyclovir for treatment of zoster.²² Valacyclovir rather than acyclovir may be used in children older than age 2 years with chickenpox.

The dose of valacyclovir is 20 mg/kg per dose orally three times a day for 5 days, not to exceed 1 g per dose 3 times daily.

Of concern about the potential widespread use of acyclovir is that drug resistance may develop. At present, resistance is less a problem with VZV than with HSV, but VZV resistant to acyclovir has been reported in a few patients with underlying AIDS.¹²⁷ Two vaccinated children with neuroblastoma who developed zoster caused by the Oka strain that became resistant to acyclovir after prolonged treatment have also been described.^{33,155} Foscarnet was licensed by the Food and Drug Administration for the treatment of VZV infections that are resistant to acyclovir and famciclovir. Foscarnet inhibits the synthesis of VZV DNA polymerase.^{205,206,220} Intravenous foscarnet is given at a dosage of 180 mg/kg per day in two divided doses, adjusted according to renal function. The main toxicity of foscarnet is renal damage and electrolyte imbalance.⁸³

PROGNOSIS

The prognosis of varicella and zoster is excellent in children without underlying health problems. The outlook for immunocompromised patients receiving antiviral chemotherapy also is good, especially if treatment is begun at an early stage of the illness. In general, zoster carries a better prognosis than varicella, possibly because it is a secondary infection. If the disease is diagnosed promptly, complications such as bacterial superinfections usually can be treated successfully with antimicrobial agents. In the pre-vaccine era, despite the availability of antiviral therapy and passive immunization, the Centers for Disease Control and Prevention (CDC) estimated that approximately 100 deaths from varicella occurred annually in the United States, mostly in children with no previous health problems. An epidemiologic study of more than 250,000 health maintenance organization records indicated that the rates of varicella in adolescents and young adults and the complication and hospitalization rates had increased between 1992 and 1995 by a factor of approximately 5.⁵¹

The widespread use of varicella vaccine in the United States decreased the morbidity and mortality rates from chickenpox substantially. By 2000, in the three sentinel communities in the United States, vaccine coverage among children 19 to 35 months was more than 80%, and reported varicella cases had declined by roughly 70% to 80% compared with the prevaccine era. Hospitalizations for varicella also declined by approximately 80%. The greatest declines occurred in young children.¹⁸⁴ Deaths from varicella have become rare.¹⁷⁰ At present, more than 90% of children in the United States are routinely vaccinated against varicella.⁴¹

PREVENTION

VZV is such an infectious agent that general measures are not useful for prevention of varicella in susceptible individuals. Some protection, however, can be achieved by isolation of hospitalized patients. Hospitalized patients with active VZV infection should be admitted to a private room, preferably with negative-pressure ventilation, and hospital personnel and visitors should wash their hands before and after entering the room and wear masks, gowns, and gloves while in it. The CDC now recommends postexposure vaccination for healthy varicella-susceptible exposed individuals.³⁷

Passive Immunization Against Varicella

Varicella-susceptible children at high risk for development of severe chickenpox should be passively immunized if they are closely exposed to VZV. Passive immunization may be lifesaving; it may modify varicella or prevent it.

Passive immunization is indicated for varicella-susceptible individuals who have been closely exposed to varicella or zoster and are at high risk for development of severe chickenpox. This population includes immunocompromised children and adults, pregnant women, neonates whose mothers have active varicella at the time of delivery, and premature infants of less than 28 weeks' gestation or who weighed less than 1000 g at birth. Children at high risk should be considered to be susceptible to varicella if they have no history of having had chickenpox or

vaccination. False-positive antibody test results may occur in immunocompromised individuals, and, therefore, susceptible children may be identified serologically as immune; hence, a history of illness is a preferred indication of these patients' immune status. Passive immunization usually is reserved for VZV-exposed adults only if they have been proved serologically to be susceptible to chickenpox, because most adults with a negative history of varicella raised in the continental United States are immune. Immigrants who came from countries with tropical climates, however, may be presumed to be susceptible without a history of varicella because the disease spreads less readily in tropical countries than in those with temperate climates.

Patients with HIV infection, especially those with AIDS, have some increased risk for development of severe varicella, and their management should be similar to that of immunocompromised children with regard to passive immunization. Even children who are receiving intravenous globulin for treatment of HIV infection should receive passive immunization if they have no past history of varicella and close exposure has occurred.

Infants whose mothers have an onset of chickenpox 5 days or less before delivery or within 48 hours after delivery should be given passive immunization as soon as possible after birth.⁸⁵ The transplacental route of infection and the immaturity of the immune system probably account for the severity of varicella in these infants.⁸⁵ Attack rates for varicella as high as 50% in infants exposed to mothers who have varicella have been reported, despite their having passive immunization.^{85,197} Passively immunized infants should be observed closely, but usually they can be managed as outpatients. Intravenous acyclovir should be reserved for the rare, passively immunized infant with varicella in whom an extensive rash (>200 vesicles) or possible pneumonia develops.¹⁶

Passive immunization need not be given to full-term infants who are exposed to VZV after they are 48 hours old. Passive immunization is optional for neonates (<1 week old) if their siblings at home have active varicella. Infants exposed to VZV after birth almost always have mild varicella. Although the reported mortality rate from varicella in children younger than 1 year is four times that in older children, both rates are exceedingly low—eight per 100,000 cases and two per 100,000 cases, respectively.¹⁹⁶ The mortality rate for adults and for leukemic children receiving chemotherapy, in contrast, is 20 and 1000 times higher, respectively.¹⁹⁵ Passive immunization is not useful to treat VZV infections or to prevent zoster. Whether it is useful for pregnant varicella-susceptible women who have been exposed to VZV to protect the fetus from developing the congenital varicella syndrome is uncertain but possible.⁵⁶

Historically, varicella-zoster immune globulin (VZIG), was used successfully for passive immunization for many years. Because of limited requests for VZIG since licensure of varicella vaccine, however, VZIG no longer is being produced in the United States. Another product, varicella immune globulin (human), VariZIG, manufactured in Canada, is now used for passive immunization. VariZIG can be obtained from FFF Enterprises (Temecula, CA; 800-843-7477) or ASD Healthcare (Frisco, TX; 800-746-6273). An alternative to VariZIG is intravenous immune globulin 400 mg/kg.

Although passive immunization has been shown to be effective when it is given within 4 days and perhaps as long as 5 days, it should be administered as soon as possible after an exposure to VZV.^{3,40} In 2012, the CDC has recommended passive immunization for as long as 10 days after close exposure to VZV (based on limited data) with the possibility that it will have a salutary effect.^{43,44} The dose is 1 vial or 125 U for every 10 kg of body weight, with a maximal dosage of 5 vials or 625 U, given intramuscularly. VariZIG should be readministered to high-risk susceptible individuals who are closely reexposed 3 weeks after a first dose.³

Active Immunization Against Varicella

A live attenuated varicella vaccine, the Oka strain, was developed in Japan more than 40 years ago.¹⁶⁸ It was licensed in the United States in 1995 for universal immunization of healthy children and adults who are susceptible to varicella^{41,36} and has proved to be extremely safe and well tolerated.^{25,41,46,79,217} Varicella vaccine is labile. The lyophilized vaccine must be stored frozen at an average temperature of 5°F or colder. The

freezer must have its own door; frost-free freezers are acceptable. Prior to use, the vaccine must be diluted with its supplied diluent and administered subcutaneously to the patient within 30 minutes to preserve its potency.⁴¹

Originally a monovalent formulation of varicella vaccine was licensed in the United States. Currently two licensed varicella vaccine formulations are available in the United States, both produced by Merck. Monovalent varicella vaccine, which contains 1350 plaque-forming units (PFU) at expiry, is recommended for healthy varicella-susceptible persons above the age of 12 months. A combination vaccine, MMRV, which was licensed in 2005, contains a larger amount of VZV than Varivax, approximately 10,000 PFU at expiry. MMRV is recommended for healthy children between 1 and 12 years of age. It should not be given to adults. Varicella vaccines used worldwide are the Oka strain, made and sold by various manufacturers, and appear to be similar to the vaccine used in the United States. The only country in which a different but similar strain of vaccine virus is available is South Korea.¹³⁹

Safety

The most frequent adverse reaction to vaccination is a mild rash that develops several weeks later in approximately 5% of healthy children, particularly after the first dose.^{96,100,217,244} These rashes can be serious in immunocompromised children who are vaccinated inadvertently,^{84,89,217} but usually respond to antiviral therapy. When vaccinees develop rash from the Oka strain, the potential for transmission of the vaccine virus exists, but transmission is extremely rare from healthy individuals, with fewer than 12 reported instances from healthy vaccinated individuals after more than 20 years of routine immunization of more than 80 million American children.^{41,79,109,217} In contrast, the rate of transmission of the Oka strain was 14% after household exposure from vaccinees with underlying leukemia who had a rash and exposed their susceptible healthy siblings.²³³

It was observed that the incidence of febrile seizures was double that in children from 1 to 2 years of age in the 5 to 12 days after MMRV compared with monovalent varicella vaccine (one extra febrile seizure for every 2500 vaccinees).¹⁴¹ After careful consideration the CDC recommended that for the first dose of measles, mumps, rubella, and varicella at age 12 to 47 months, either MMR vaccine and monovalent varicella vaccine or MMRV may be used. Providers are advised to discuss the risks and benefits of each of the two choices with the infant's parent or caregiver, particularly if it is anticipated to give MMRV; the CDC favors giving MMR and varicella vaccines in separate sites. For the second doses, at any age, and if the first dose is given at age 4 years or older, MMRV is preferred.⁴²

Few serious neurologic events have been causally demonstrated to be connected to varicella vaccine. There have been nine reports of herpes zoster due to the Oka strain with accompanying meningitis (VZV DNA found in CSF by PCR assay) in a group of healthy and immunocompromised patients, all of whom had a rash and recovered with antiviral therapy.²³ It is well known that meningitis may also accompany herpes zoster caused by wild-type VZV,^{45,101,192,222,224} so it is unclear whether these nine patients should be classified as having a vaccine-associated adverse event or not. Because there is no known denominator, the incidence of these complications after vaccination is not known, but it appears to be rare. Transient cerebellar ataxia has been temporally associated with vaccination, but its connection to VZV has not been proven.^{79,217}

Effectiveness

Live attenuated varicella vaccine is highly effective in healthy children and adults, but not all vaccinees are completely protected. From 10% to 20% of children given one dose may develop a modified breakthrough illness after intimate exposure to VZV. Varicella vaccine has, however, been 97% effective in preventing severe varicella.^{237,236} The vaccine is also highly effective in adults; after two doses, more than 75% are completely protected from varicella after household exposure to the virus.^{1,96,207} Severe wild-type varicella in vaccinated adults is very rare.

Originally, it was observed that approximately 85% of healthy children are protected after only one dose of vaccine,^{145,237,236,244} and there was little concern about breakthrough varicella because it had been found

to be almost always a modified illness. There was no significant waning of immunity in a case-control study with laboratory verification of varicella.²³⁷ Loss of VZV antibodies, moreover, occurs rarely in healthy vaccinated children, some of whom have been monitored for as long as 20 years after immunization.^{10,12,55,145,219,239,253}

Beginning in approximately 2000, however, breakthrough varicella became a growing concern in the United States. The incidence of varicella in sentinel geographic areas where active surveillance was being performed revealed that although the incidence of disease fell after 1995, it leveled off at a low rate in about 2000.^{214,215} The number of reports of outbreaks of varicella among vaccinated children was, moreover, increasing; some of these studies indicated vaccine effectiveness as low as 44% and 56%, although most showed 80% to 85% effectiveness.^{80,151} Also recognized was that children with breakthrough infections could spread wild-type VZV to contacts almost as efficiently as unvaccinated children with varicella.²¹⁵ Attempts at outbreak control with second doses of varicella vaccine during outbreaks proved to be expensive and complicated.¹⁶⁹ Finally, one study indicated that the FAMA seroconversion rate after one dose of vaccine could be as low as 76%, indicating an unexpectedly high rate of primary vaccine failure after one dose of vaccine.¹⁷⁸ The fear was that without a second routine dose, a gradual accumulation of susceptible young adults would develop as a result of primary vaccine failure and would be at risk to develop severe chickenpox.

In the light of all these problems, a second dose of varicella vaccine was recommended for all children, not just those older than 12 years, by the CDC in June 2006. Early studies exploring immune responses to two doses had indicated the safety of a second dose and a marked boost in immunity and the seroconversion rate afterward. An interval of 4 to 6 years between the first and second doses was recommended in 2007, but there was flexibility in that the second dose could be administered at any time 1 month after the first dose.⁴¹ Catch-up immunization was also recommended for children who received only one dose of varicella vaccine.⁴¹ With the institution of two routine doses, protection achieved 98% in a case-control study,²¹⁶ and the incidence of varicella was reported to have decreased significantly in Connecticut.¹³⁴

Because the risk from wild-type VZV is greater than is the risk from vaccine-type VZV, immunization is recommended for health care workers and persons whose varicella-susceptible family members are immunocompromised or pregnant.⁴¹ Varicella vaccine is recommended only for healthy persons. Vaccinees in whom an extensive VZV rash develops within 2 to 3 weeks after immunization are likely to have wild-type infection.

In such situations, PCR and restriction fragment length polymorphism analysis can be used to differentiate between wild-type and vaccine-type VZV. Passive immunization could be considered for immunocompromised individuals inadvertently exposed to a vaccinee with rash resembling chickenpox that might be caused by wild-type VZV.

Most states now require varicella vaccination for children to attend daycare or school. In geographic areas where vaccine use in children younger than 3 years is 70% or more, the incidence of varicella has decreased sharply, not only in the vaccinated group but also in all age groups, a process indicative of herd immunity.^{214,221} As has been mentioned, the incidence of zoster appears to be less of a problem after immunization than after natural infection in vaccinated immunocompromised individuals and in healthy vaccinees.^{191,242}

HIV-infected children may be immunized with monovalent varicella vaccine if they are free of symptoms and have 15% or more CD4 T lymphocytes (for children >8 years, a CD4 T lymphocyte level of ≥ 200 cells/ μ L is used). For these children, varicella vaccine has been shown to be safe, immunogenic, and effective.^{41,221}

Individuals who are immunocompromised should not be given live attenuated varicella vaccine because rare severe and even fatal varicella has been reported in these individuals.²³ It is hoped that immunocompromised persons will be protected by herd immunity. Those who become infected by WT VZV should be promptly treated with intravenous acyclovir. Mortality from VZV has decreased significantly since licensure of the vaccine with little or no evidence of waning immunity.^{20,153,170}

Drug Prophylaxis

Prophylaxis of varicella in exposed persons may be achieved by the administration of acyclovir.^{13,124,159,229} This approach is not recommended often, however, because the optimal dosage and timing of administration have not been studied in large groups of children, nor is it known whether long-term maintenance of immunity exists in all children. In the United States, prevention of varicella by vaccination is a preferable approach. Long-term acyclovir therapy may be used to prevent the development of zoster in patients who have undergone bone marrow transplantation; however, its value is questionable because zoster commonly develops after administration of acyclovir is stopped.³⁸

Smallpox (Variola Virus)

James D. Cherry

Smallpox is a dreaded febrile exanthematous disease caused by the orthopoxvirus variola virus.^{5,6,10,23,26,37} After an extensive decade-long World Health Organization (WHO) program to eradicate smallpox, the world was certified free of smallpox in 1979.^{17,95} Increased concern relating to biologic terrorism occurred during the 1990s, and the events of September 11, 2001, and immediately thereafter brought home the potential reality of this threat for the present and future.^{3,24,50,49,53,69,72,88,95}

HISTORY*

Evidence suggests that endemic smallpox was occurring before 1500 BCE. Three mummies dating from the 18th to the 20th dynasties in

Egypt had pustular lesions all over their bodies.³⁶ Reliable written accounts of smallpox first appeared during the 4th century. Smallpox was differentiated from measles in 340 by Ko Hung in China. At that time in China, smallpox was an established endemic disease that had come from the west 300 years earlier. During the period from 340 to 1000, the disease was described in Egypt, India, Korea, Japan, southern Europe, and North Africa. A major contributor to the spread of smallpox was the great Islamic expansion across North Africa and into Spain in the 7th and 8th centuries.

By the year 1000, smallpox probably was endemic in populated areas of Europe, Asia, and the African Mediterranean countries. Smallpox was established further in northern Europe by the population movements related to the Crusades. By the 16th century, smallpox was a serious disease in Europe, as indicated by death statistics in Geneva, London, and Sweden. In London during the 17th century, approximately 10% of yearly deaths were attributed to smallpox.

The disease was introduced into the American colonies in 1507 and into Mexico soon thereafter. Epidemics of smallpox posed serious problems for the colonists as well as for the Native Americans. These epidemics also may have been important in certain stages of the American Revolution.^{6,38} Smallpox persisted in the United States and Mexico until the 1940s and 1950s, respectively, despite concerted efforts to eliminate the problem.

Soon after this disease was recognized, the Chinese are reported to have made efforts to prevent it. The technique used presumably was variolation, the intentional intranasal or intracutaneous inoculation of susceptible persons with vesicular fluid or crusts from patients with smallpox. This technique apparently originated in China and subsequently was used in many countries, including the United States. As recently as 1968 and 1969, isolated instances of the use of variolation were noted in remote areas of Africa and Asia.^{38,54}

After making his observations in 1796 on the immunity against smallpox that was conferred by inoculation with material obtained from cowpox lesions, Jenner extended his research to include intentional and deliberate exposure of some of those persons immunized with cowpox. This strategy provided convincing evidence of solid protection against smallpox.⁶⁰ Encouraged by the results, Jenner predicted in 1801 the ultimate eradication of smallpox, a remarkable prediction indeed.^{38,48}

The Intensified Smallpox Eradication Program of the WHO, established in 1967, initiated remarkable progress toward total global eradication of this disease.⁵² Several factors responsible for this rapid progress included emphasis on surveillance of disease, with containment rather than routine vaccination; improved vaccines and vaccination technology; and sound administrative and fiscal support.^{38,39,51,52,64} Of the more than 30 countries in 1967 in which smallpox was endemic, the disease persisted in only five in 1975 and in two in 1977. The world's last case of endemic smallpox occurred on October 31, 1977, in Merca, Somalia.³¹ A year later, in 1978, a photographer working at the University of Birmingham in England was infected with a laboratory strain of smallpox virus and died.⁹¹

After the worldwide eradication of smallpox was achieved, the World Health Assembly (WHA) in 1980 recommended that all countries cease vaccination.⁹⁵ Subsequently, a WHO expert committee recommended that all laboratories throughout the world destroy their stocks of variola virus or transfer them into either of two WHO reference laboratories.⁵³ The laboratories were the Russian State Research Center on Virology and Biotechnology, Koltsovo, Novosibirsk Region, and the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia.⁹ Reportedly, all countries complied with this recommendation.

The WHO committee at a later date recommended that all variola virus stocks be destroyed by 1999, and the WHA concurred with this recommendation.¹¹ In 1998, a committee of the Institute of Medicine reviewed the possible importance of retaining variola virus for research purposes.⁵⁸ In May 1999, the WHA agreed to postpone the destruction of all variola stocks until 2002.⁴⁰ In 2005, the WHA again voted not to destroy smallpox stocks.⁸⁵ In May 2011, the WHA agreed to postpone setting a date for destruction of smallpox stocks.^{86,94} It was to be considered again at the 67th WHA meeting in 2014. Prior to the WHA meeting a number of significant events and concerns had arisen, and therefore the decision on the fate of the smallpox stocks was again put

off until 2016 at the earliest.^{70,80} On July 1, 2015, scientists found six vials, labeled "variola" in a storage area in the Food and Drug Administration (FDA). These vials were then shipped to CDC for study. Another WHO concern was whether smallpox virus could be synthesized from scratch by those who might have nefarious intentions. If this were the case, it would be important to preserve the virus stocks so that research could be continued to develop counterviruses against terrorist attacks.^{2,29,59}

Also of note was the finding of variola virus DNA in a 300-year-old Siberian mummy.^{8,87} In this instance, no intact virus was found; however, finding complete viral genome in other studies of mummies would appear to be a possibility. At the present time, research using the virus is being conducted in the United States and Russia. This research is related to the development of safer vaccines and to antiviral agents.

In the early 1990s, evidence revealed that during the previous 10 years, the Soviet government apparently had developed a successful program to produce variola virus for use as a biologic weapon.^{53,84} In the late 1990s, concern increased with regard to bioterrorism and, in particular, with the possibility that Russian expertise and equipment could have fallen into non-Russian hands because financial support for laboratories and workers had declined.

Smallpox was used as a biologic weapon almost 250 years ago.^{4,28} In the French and Indian Wars (1754–1767), British forces sent smallpox-contaminated blankets and handkerchiefs to the Native Americans surrounding Fort Pitt in the summer of 1763.

ETIOLOGY

Smallpox is caused by a variola virus, an orthopoxvirus.^{37,52,74} The virus particles are brick shaped and measure 250 to 300 × 200 to 250 × 100 nm; the size and shape are similar for all orthopoxviruses. The distinctive appearance is helpful in rapidly identifying members of this virus group by electron microscopy of vesicular fluid or crusts. The virus is stable when dried and may remain viable for long periods in dried crusts and indefinitely under freeze-drying techniques in the laboratory. It is propagated readily on the chorioallantoic membrane of embryonated eggs and in a variety of mammalian cell cultures.

EPIDEMIOLOGY

In infected patients, variola virus was found in respiratory secretions and in vesicular fluid from skin lesions. Transmission usually occurred after close personal contact, but airborne spread also could occur.^{7,52,53,91} Patients with smallpox were most infectious from the onset through the first 7 to 10 days of rash.

All persons were susceptible to smallpox unless they previously had been infected with variola virus itself or with cowpox or vaccinia virus. Thus, the occurrence of smallpox depended entirely on the presence of a human source of infection and effective exposure of susceptible persons. The age distribution of cases varied in individual countries, depending largely on vaccination practices. Preschool-aged children often were not vaccinated and thus had the greatest prevalence of disease.

The seasonal influence was substantial and perhaps is shown best by the spread of disease after the winter and spring introduction of smallpox into Europe; spread of infection was more than 30 times as great after the introduction of infection into European nations between December and May, in contrast to substantially less frequent spread after introduction between June and November.⁹⁶

Substantial contrast in case-fatality rates was recognized in different geographic areas; these differences did not seem to depend on the supportive care available and did not appear to be related to ethnic or specific resistance factors. The only logical explanation for these different rates was substantial differences in the virulence of the virus prevalent in the regions. The mildest form of smallpox, described as *variola minor*, or *alastrim*, was prevalent in Brazil, Ethiopia, and adjacent countries. Case-fatality rates of 1% or less were customary, and permanent residual scarring and blindness were most unusual occurrences. In other areas of Africa and Indonesia, the disease appeared to be of intermediate severity, whereas on the Indian subcontinent, case-fatality rates were as high as 30%, with residual permanent scarring, blindness, and other sequelae occurring frequently in those who survived the acute illness.³⁸

PATHOLOGY

The characteristic pathologic lesions affected the skin and mucous membranes. They involved the deeper layers of the skin and progressed through macular, papular, vesicular, and pustular stages, with the subsequent formation of crusts. Lesions similar to those on the skin also were found in the lower respiratory and gastrointestinal tracts.

Secondary bacterial infection occurred frequently and often affected the skin and lungs. Hemorrhagic complications (hemorrhagic smallpox) were not uncommon events.

CLINICAL MANIFESTATIONS

After an incubation period of 7 to 17 days, the disease began abruptly with fever (i.e., temperatures between 38.9°C and 40.5°C [102°F and 105°F]), headache, and marked malaise.¹¹ Backache and muscle pain were prominent symptoms. Nausea, vomiting, and abdominal pain also were present.^{34,52,63,73}

After these prodromal signs and symptoms were present for 2 to 4 days, the fever usually decreased, and the characteristic cutaneous eruption appeared. The rash was most extensive on the face and extremities, and the individual lesions passed through the stages of macules and papules; by the third or fourth day, they clearly were vesicular. Lesions in a single area of the body were characteristically at the same stage of development.

By the sixth day, the vesicular fluid usually was cloudy and the individual pustules frequently were umbilicated. Pustules often converged and become confluent. By the tenth day, the individual lesions began to dry and formed characteristic crusts that remained intact for several days before they were shed. The patient's temperature customarily fell during the early appearance of the rash, although the fever usually returned. Significant fever that persisted after the tenth or twelfth day of disease suggested the presence of bacterial superinfection.

Although most cases were similar to this description, which was characteristic of the ordinary type of smallpox, other clinical variations were described. The hemorrhagic type was the most severe form, with a case-fatality rate that approached 100%. In this form, hemorrhagic manifestations appeared during the prodromal stage, with extensive cutaneous extravasation of blood and bleeding from the various body orifices. Death usually occurred within the first week of illness, and, frequently few typical diagnostic lesions appeared on the skin surfaces before death ensued. Fortunately, this form of disease occurred in only 2% or 3% of the total cases of variola major in Asia, and it rarely was seen elsewhere.

A flat variety had been reported in approximately 6% of cases observed in India. In this variety, the cutaneous lesions remained flat and soft to the touch, in contrast to the ordinary variety; these lesions characteristically resolved without pustulation. This form was associated with case-fatality rates of 75% to 96%.³⁸

A modified form of disease occurred almost exclusively in previously vaccinated persons. Although the prodromal illness often was severe, skin lesions were few, evolved rapidly, and were more superficial. The prognosis was excellent.

The mildest form of the disease, *alastrim*, or *variola minor*, was caused by a specific variola virus having less pathogenicity in humans. Serious forms of the illness, as with *variola major*, were unusual occurrences. The skin lesions tended to be superficial, and the clinical course resembled that of *varicella*, with the exception of the distribution of cutaneous lesions. These lesions involved the face and extremities, in contrast to the characteristic central body distribution of *varicella*. Residual scarring, if it occurred at all, usually reflected secondary bacterial infection of individual lesions.

In recently vaccinated persons, asymptomatic infection with variola virus after exposure had been demonstrated by increases in antibody titer against the virus when acute and convalescent sera were tested. This uncommon event was of neither clinical nor epidemiologic significance.

Complications included hemorrhagic events and various secondary bacterial infections, including *impetigo*, *pneumonia*, *empyema*, and *otitis media*. *Nephritis* and *arthritis* with permanent joint changes were described.

DIFFERENTIAL DIAGNOSIS

The typical course, the characteristic cutaneous lesions, and the presence of other cases after contact 7 to 17 days earlier left little doubt about the etiologic agent. *Varicella* presented the greatest problem in differential diagnosis, particularly from the *variola minor*, or *alastrim*, form of the disease, but the distribution of cutaneous lesions for each condition was characteristic. Generalized *vaccinia* or *eczema vaccinatum* was distinguished by a history of exposure to *vaccinia* virus, previous skin lesions, and the distribution of the rash. *Impetigo* (especially the bullous variety caused by *staphylococcal* infection), *scabies*, secondary *syphilis*, and *yaws* were other considerations. Usually, little difficulty was encountered clinically in distinguishing among these infections.

Monkeypox can be clinically similar to smallpox, and, therefore, specific laboratory procedures are required for diagnosis (see Chapter 164). Other conditions included in the differential diagnosis were *erythema multiforme*, *pityriasis rosea*, *measles*, *rickettsialpox*, *disseminated herpes simplex* infection, *syphilis*, *enteroviral exanthems*, and bacterial, viral, and *rickettsial* petechial and purpuric rashes.

SPECIFIC DIAGNOSIS

Several laboratory procedures are available to provide specific and accurate diagnosis. Vesicular fluid, crusts, or scrapings from skin lesions reveal the characteristic brick-shaped viral particles of the *variola-vaccinia* virus group when examined by electron microscopy. These orthopoxviruses differ in appearance from the *herpesviruses*, which in the past were the agents most frequently confused with smallpox. Electron microscopy is precise and rapid and is preferred when facilities for this examination are available.²⁷ Smallpox virus DNA also can be identified rapidly by polymerase chain reaction (PCR).^{34,35,62,81} PCR has an advantage over electron microscopy in that it can specifically distinguish smallpox virus from the other orthopoxviruses.

Orthopoxviruses may be recovered and propagated on the chorioallantoic membrane of embryonated eggs or in tissue culture.³⁴ Virus recovery requires more time (3 to 7 days) than the direct antigen-detection tests, but it provides the specific active virus required for differentiation among the various orthopoxvirus types.^{75,77} Infection also can be determined serologically by using acute-phase and convalescent-phase sera in enzyme-linked immunosorbent assay (ELISA), Western blotting, or virus neutralization assays.³⁴

The specific diagnosis of a disease that does not currently exist anywhere in the world presents unique challenges. Recognizing these challenges, the CDC has a diagnosis and evaluation plan with laboratory testing recommendations (<http://emergency.cdc.gov/agent/smallpox/diagnosis>).

TREATMENT

Therapy primarily was supportive and symptomatic. The skin was kept clean, the bed linen was changed at regular intervals, and local or systemic therapy was provided for the frequent bacterial complications. Attention given to appropriate fluid and nutritional support was required.

Methisazone, convalescent smallpox serum, and *vaccinia* immune globulin (VIG) were effective in preventing the disease after exposure, but no evidence showed that these agents altered the course of the disease once symptoms occurred.⁶¹ *Idoxuridine* was used for corneal lesions.⁶

At the present time the United States has a stockpile of VIG, which is produced by Cangene Corporation in Canada (<http://www.cdc.gov/laboratory/drugservice/formulary.html>).⁹³ This product is presently available for the treatment of smallpox vaccination complications (i.e., *eczema vaccinatum*, *vaccinia necrosum*, or severe generalized *vaccinia*). In the event of a biological terrorism smallpox release, it is assumed that VIG would be available for treatment.

Studies with the antivirals *cidofovir*, ST-246, and CMX001 show broad antiviral activity against orthopoxviruses.^{1,24,68,73,78} Through the Project BioShield Act of 2004, 1.7 million doses of ST-246 have been stockpiled.

TABLE 163.1 Rates of Reported Complications Associated With Vaccinia Vaccination (Cases/Million Vaccinations)

Age (y) and Status Total ^a	Inadvertent Inoculation	Generalized Vaccinia	Eczema Vaccinatum	Progressive Vaccinia	Postvaccinial Encephalitis	Total
Primary						
<1	507.0	394.4	14.1	— ^b	42.3	1549.3
1–4	577.3	233.4	44.2	3.2	9.5	1261.8
5–19	371.2	139.7	34.9	—	8.7	855.9
≥20	606.1	212.1	30.3	—	—	1515.2
Overall rates	529.2	241.5	38.5	1.5	12.3	1253.8
Revaccination						
<1	—	—	—	—	—	—
1–4	109.1	—	—	—	—	200.0
5–19	47.7	9.9	2.0	—	—	85.5
≥20	25.0	9.1	4.5	6.8	4.5	113.6
Overall rates	42.1	9.0	3.0	3.0	2.0	108.2

^aRates of overall complications by age group include complications not provided in this table, including severe local reactions, bacterial superinfection of the vaccination site, and erythema multiforme.

^bNo instances of this complication were identified during the 1968 10-state survey.

From Lane JM, Ruben FL, Neff JM, et al. Complications of smallpox vaccination, 1968: results of 10 statewide surveys. *J Infect Dis.* 1970;122:303–309.

PREVENTION

Active Immunization

In the 20th century, many strains of vaccinia virus were used in the effective prophylaxis of smallpox, which led to the control and then eradication of smallpox from the world. After smallpox was eliminated from the United States and Western Europe, general concern shifted to morbidity and mortality resulting from smallpox vaccines.^{45,66,67} It was realized that the risk for smallpox was remote and that vaccine reactions were significant (Table 163.1). Because of this, routine smallpox vaccination was discontinued in the United States in the 1970s.

In the late 1990s, concerns arose that smallpox could be used as a weapon of bioterrorism. The events of September 11, 2001, and immediately thereafter highlighted the potential reality of this threat.^{3,24,50,49,53,72,88} Estimates were that probably less than 20% of the US population had any immunity.⁵⁰ These concerns led to recommendations by the Advisory Committee on Immunization Practices (ACIP) for the use of smallpox vaccine to protect persons who may need to work with orthopoxviruses and to prepare for a possible bioterrorism attack.¹⁶ The government took steps to prepare the country in the event of a bioterrorist attack involving smallpox. These measures included building an adequate supply of vaccine, enhancing the laboratory capacity for diagnosis of variola and vaccinia virus infection, and training health care and public health personnel.⁴⁴

Through the *Project BioShield Act*, the United States has an ample supply of smallpox vaccine.⁷⁶ This is presently available for immunization of selected people (e.g., first responders and laboratory workers) and would be available if a bioterrorist attack were to occur.⁷⁹ This stockpile includes ACAM 2000, which is prepared in cell culture, and a modified vaccinia, Ankara (MVA), a new vaccine. This vaccine is thought to be safer than conventional smallpox vaccines, and it was purchased by the United States to be used in immunocompromised persons if a terrorist smallpox release occurred.^{43,49,51,89}

The primary strategy used in the past to control an outbreak of smallpox and to interdict the transmission of virus was known as a *surveillance and containment (ring vaccination)* strategy. This strategy identified infected persons through intensive surveillance and subsequently both isolated the individuals with the disease and vaccinated household and close contacts of the infected patient. Vaccination also was recommended for contacts of the primary contact with the patient (secondary contacts). This strategy was instrumental in the eradication of smallpox as a naturally occurring disease. Depending on the size of any smallpox outbreak and the availability of resources for rapid and thorough contact tracing, ring vaccination was supplemented previously in areas with identified smallpox cases to include voluntary vaccination

of all individuals without vaccine contraindications. This strategy was pursued to expand the ring of immune individuals within an outbreak area and to reduce further the chance of any secondary transmission of smallpox to patients before they could be identified and isolated.

The CDC developed protocols to permit rapid, simultaneous delivery of smallpox vaccine to every state in the US territory within 12 to 24 hours. Smallpox response planning at the federal level has been conveyed to state and local health departments to address the rapid distribution of the vaccine if vaccination programs are suggested.

The CDC currently recommends that cases of febrile rash illnesses for which smallpox is considered in the differential diagnosis be reported immediately to local or state health departments or both. After evaluation is performed by local or state health departments, if smallpox laboratory diagnostics are considered necessary, the CDC Rash Illness Evaluation Team should be consulted. At this time, laboratory confirmation for smallpox is available routinely only at the CDC. Both a clinical consultation and a preliminary laboratory diagnosis can be completed within a period of 8 to 24 hours.

In the present bioterrorism era the CDC and the ACIP have devoted considerable effort into the diagnosis of smallpox and have looked at risks and benefits of smallpox immunization programs. To assist public health and other medical personnel in evaluating the possibility of smallpox in patients with febrile rash illnesses, the CDC developed a rash illness assessment algorithm (<http://emergency.cdc.gov/agent/smallpox/diagnosis/riskalgorithm/>).

Medical evaluation of the risks for acquiring smallpox under current conditions and in the absence of a case of smallpox or a confirmed smallpox bioterrorism threat in contrast to the potential risks for developing vaccine complications was such that the ACIP concluded that vaccination of the general population was not recommended because the potential benefits of vaccination did not outweigh the risks for vaccine complications. In 2001, the ACIP recommended smallpox vaccine for laboratory workers who directly handle (1) cultures or (2) animals contaminated or infected with vaccinia, recombinant vaccinia viruses, or other orthopoxviruses that infect humans (e.g., monkeypox and cowpox).¹⁶ Other health care workers (e.g., physicians and nurses) whose contact with these viruses is limited to contaminated material (e.g., dressings) but who adhere to appropriate infection control measures are at lower risk for inadvertently acquiring infection than are laboratory workers. However, because a theoretical risk for developing infection does exist, vaccination may be considered for this group. Because of the low risk for developing infection, vaccination was not recommended for persons who do not handle virus cultures or materials directly or who do not work with animals contaminated or infected with these viruses. According to available data on the persistence of neutralizing

antibody after vaccination, persons working with vaccinia, recombinant vaccinia viruses, or other nonvariola orthopoxviruses should be revaccinated every 10 years.

In 2003, the ACIP and the Healthcare Infection Control Practices Advisory Committee (HICPAC) published supplemental recommendations for using smallpox vaccine in a pre-event vaccination program.¹⁸ A summary of these recommendations is presented here:

*To facilitate preparedness and response, smallpox vaccination is recommended for persons designated by public health authorities to conduct investigation and follow-up of initial smallpox cases that could necessitate direct patient contact.*¹⁸ The ACIP recommended that each state and territory establish and maintain more than one smallpox response team. The ACIP and the HICPAC recommended that each acute-care hospital identify health care workers who can be vaccinated and trained to provide direct medical care for the first smallpox patients requiring hospital admission and to evaluate and manage patients who are suspected as having smallpox. When feasible, the first-stage vaccination program was to include previously vaccinated health care personnel to decrease the potential for adverse events. Additionally, persons administering smallpox vaccine in this pre-event vaccination program were to be vaccinated.

Side Effects and Adverse Events of Smallpox Vaccines

The risk for adverse events resulting from smallpox vaccine today is presumed potentially to be at least as great, in terms of severity and frequency of events, as during the era when universal vaccinia vaccination was performed.^{19,45} One can suspect that the number of adverse reactions may be increased in frequency in the current era in contrast to the 1960s and 1970s because a larger proportion of the population of the United States and the world may have an inherited or acquired a form of immunodeficiency or may be receiving a variety of agents that suppress the immune system. Factors thought to predispose to development of adverse events include pregnancy or breast-feeding, extensive skin eruptions, atopic dermatitis, T-cell immune defect, immunosuppressive therapy, inflammatory or disruptive diseases of the cornea, and age younger than 1 year.¹⁹

Fever occurs commonly after smallpox vaccination. As many as 70% of children have 1 or more days with a temperature of 37.8°C (100°F) or higher 4 to 14 days after receiving primary vaccination,^{22,71} and 15% to 20% have temperatures of 38.9°C (102°F) or higher. After receiving revaccination, 35% of children have temperatures of 37.8°C (100°F) or higher, and 5% have temperatures of 38.9°C (102°F) or higher.⁷¹ Fever after vaccination or revaccination occurs less commonly in adults than in children.

An erythematous or urticarial rash may occur approximately 10 days after receipt of primary vaccination. The vaccinee usually is afebrile, and the rash resolves spontaneously within 2 to 4 days. Rarely, bullous erythema multiforme (Stevens-Johnson syndrome) occurs.⁶³

Inadvertent inoculation at other sites, the most frequent complication of vaccinia vaccination, accounts for approximately half of all complications of primary vaccination and revaccination.¹⁷ Inadvertent inoculation usually results from autoinoculation of vaccine virus transferred from the site of vaccination. The most common sites involved are the face, eyelid, nose, mouth, genitalia, and rectum. Most lesions heal without specific therapy, but VIG may be useful for cases of ocular implantation.

Generalized vaccinia in persons who have no underlying illness is characterized by a vesicular rash of varying extent. The rash generally is self-limited and requires little or no therapy, except in patients whose conditions appear to be toxic or in those who have a serious underlying illness.

Other expected systemic symptoms associated with smallpox vaccination include malaise, myalgia, headache, chills, nausea, and fatigue (0.3–3%).^{41,42} Soreness at the site of the vaccination is a very common development, as are local lymphadenopathy and erythema surrounding the vaccination site.⁴⁴

Expected local events occurring relatively infrequently require symptomatic treatment. They include satellite lesions within 2.5 cm of the primary lesion, viral lymphangitis, local edema, and intense inflammation surrounding the papule.^{41,42,44}

TABLE 163.2 Number of Reported Events Associated With Smallpox Vaccination in the Military: 2002–07

Event Type	Department of Defense Experience ^a	US Military Experience ^b
Inadvertent inoculation	61	Self: 48 Transfer to contact: 21
Generalized vaccinia	43	36
Eczema vaccinatum	1	0
Progressive vaccinia	0	0
Myopericarditis	140	37
Ischemic heart disease	16	NA
Encephalitis	NA	1
Treated with VIG	6	NA
Death ^c	8	0

NA, Not applicable; VIG, vaccinia immune globulin.

^aDepartment of Defense experience: December 2002 to May 2007, 1.2 million vaccinees.²⁸

^bExperience of US military: December 2002 to May 2003, 450,293 vaccinees.⁴⁹

^cAfter review, one death was the result of an acute lupuslike illness that may have been caused by the vaccine, and others were thought to result from other causes.²⁸

More severe complications of vaccinia vaccination include eczema vaccinatum, progressive vaccinia, myopericarditis, and postvaccinial encephalitis. These complications, with the exception of myopericarditis, occur at least 10 times more often among primary vaccinees than among revaccinees and more frequently among infants than among older children and adults.^{65–67}

The number of adverse events per million doses of primary smallpox vaccination and revaccination is reported in Table 163.1. The rates described are based on surveys of vaccination-associated complications that occurred in the late 1960s in the United States. The high prevalence of immunosuppression in the United States today in contrast to the late 1960s may render the rates of vaccinia necrosum higher than in 1968. The rate of postvaccinial encephalitis in adults was difficult to document in the 1960s because very few adults were primary vaccinees. Studies performed in Europe showed higher rates of postvaccinial encephalitis in adults than in young children. Studies performed since 2002, when efforts were made to vaccinate members of the military and civilians, have shown similar rates of adverse reactions, although cardiac side effects have been more notable (Table 163.2).

Eczema vaccinatum is a localized or systemic dissemination of vaccinia virus in persons who have eczema or a history of eczema and other chronic or exfoliative skin conditions (e.g., atopic dermatitis). The illness often is mild and self-limited but may be severe and occasionally fatal. The most serious cases in vaccine recipients occur in primary vaccinees and appear to be independent of the activity of the underlying eczema.⁹⁰ Severe cases also have been observed after contact infection has occurred.

Progressive vaccinia (vaccinia necrosum) is a severe, potentially fatal illness characterized by progressive necrosis in the area of vaccination, often with metastatic lesions. It occurs almost exclusively in persons with cellular immunodeficiency.

In the 1960s, cardiac complications were reported but were not considered significant. Myopericarditis now is thought to be a true adverse event related to smallpox vaccine, although most cases resolve without further complications.^{12,32,33,98} Cases of ischemic heart disease occurring after receipt of smallpox vaccination also have been reported. Although this association has not been shown to be causal, the ACIP recommended excluding persons with cardiac disease from participation in current smallpox vaccination programs.¹⁸ The incidence of cardiac events in children is not known because the recent vaccination program has targeted adults.

The most serious complication is postvaccinial encephalitis. Usually, it affected primary vaccinees younger than 1 year. Of affected vaccinees with this complication, 15% to 25% died and 25% had permanent neurologic sequelae.^{47,66,67}

Death rarely occurred after receipt of vaccinia vaccination; reports note approximately one to two deaths per million primary vaccinations and 0.1 death per million revaccinations. Death most often was the result of postvaccinial encephalitis or progressive vaccinia.

Vaccinia may be transmitted when a recently vaccinated person has contact with a susceptible person. In the CDC's 10-state survey of complications of smallpox vaccination, the risk for transmission to contacts was 27 infections per million total vaccinations; 44% of these contact cases occurred in children age 5 years or younger.⁶⁷ Since 1980, several cases of contact transmission of vaccinia from vaccinated military recruits have been reported and include six cases transmitted by a single vaccine recipient.^{15,14,13,97} Nonmilitary secondary and tertiary transmission cases after smallpox vaccination have been noted.^{21,55,56}

Since 2001, among 1.2 million vaccinated military personnel, 61 suspected instances of transfer of vaccinia occurred, 36 of which were laboratory confirmed.³⁰ This number included two cases of tertiary transfer, one from a service member to his wife and then to their breastfeeding baby and another among male sports partners.^{20,44} Fetal vaccinia occurs rarely (<40 reported cases), but it is usually fatal.⁴⁵

More than 60% of cases of contact transmission result in uncomplicated inadvertent inoculation. Approximately 30% of these cases result in eczema vaccinatum, which may be fatal.⁶⁷ Eczema vaccinatum may be more severe in contacts than in vaccinated persons, possibly because of simultaneous multiple inoculation at several sites.^{25,66} Contact transmission rarely results in postvaccinial encephalitis or vaccinia necrosum.

Smallpox Vaccine Availability

The CDC is the only source of smallpox vaccine and VIG for civilians. In the advent of need to carry out smallpox vaccination, procedural information will be available from the CDC.

Monkeypox and Other Poxviruses

164

Samantha H. Johnston • Anne W. Rimoin

Smallpox, caused by variola virus (see Chapter 163), at one time was the most important human poxvirus disease, but this disease has been eradicated from the world. Today, only one human poxvirus, molluscum contagiosum virus, causes specific human illness. In addition, at least nine other poxviruses can cause human infections. Eight of these viruses are acquired zoonotically, and the ninth, vaccinia, is acquired by active immunization against smallpox, inadvertently by laboratory accident, or by transfer from a vaccinated person to an unvaccinated person.

PROPERTIES OF THE VIRUSES

Classification

The family *Poxviridae* has two subfamilies: *Chordopoxvirinae* (vertebrate poxviruses) and *Entomopoxvirinae* (insect poxviruses).^{55,60,125} Eight genera are included in the *Chordopoxvirinae* subfamily, and four of these genera contain species that infect humans (Table 164.1).

Structure

Poxviruses are the largest animal viruses and are discernible by light microscopy.^{15,129} In general, by electron microscopy, orthopoxviruses appear brick shaped, with a length of 350 nm and a width of 270 nm. They contain double-stranded DNA genomes that vary from 130 to 300 kbp, depending on the particular species. A 30-nm lipoprotein bilayer (envelope) surrounds the virus core. The envelope contains seven or more distinct glycoproteins. *Parapoxvirus* organisms have a different structure than do *Orthopoxvirus*, *Yatapoxvirus*, and *Molluscipoxvirus* organisms. They are ovoid and vary from 260 to 160 nm for orf virus to 300 to 190 nm for pseudocowpox virus.

SPECIFIC VIRUSES AND THEIR ILLNESSES

Monkeypox Virus

Monkeypox is a zoonotic orthopoxvirus that causes a serious smallpox-like illness in humans. Monkeypox virus was first discovered in 1958,

TABLE 164.1 Poxviruses That Can Cause Human Illness

Genus	Species
Orthopoxvirus	Variola virus
	Monkeypox virus
	Vaccinia virus
	Cowpox virus
Parapoxvirus	Orf virus
	Bovine papular stomatitis virus
	Pseudocowpox virus
	Parapox of seals
	Parapoxvirus of reindeer
Yatapoxvirus	Tanapoxvirus
	Yabapoxvirus
Molluscipoxvirus	Molluscum contagiosum virus

when it was isolated from the lesions of a generalized smallpox-like vesiculopustular disease among captive monkeys at the State Serum Institute in Copenhagen, Denmark.¹⁸¹ The disease was not recognized as being distinct from smallpox until 1970, when, after smallpox had been eliminated from many countries, a similar illness continued to circulate in rural regions of the Democratic Republic of Congo (DRC).^{46,82,91,129} Between 1970 and 1979, 55 cases of monkeypox were confirmed by the World Health Organization (WHO) in forested areas of Western and Central Africa; 44 of these cases (80%) occurred in the DRC.^{14,91,110}

In 1980, smallpox was declared eradicated by the WHO Advisory Committee on Orthopoxvirus Infections. Despite sporadic reports of human monkeypox in Africa, the WHO Advisory Committee also recommended that smallpox vaccination cease globally because of the cost and complexity of sustaining a special vaccination program for what was then a comparatively rare disease.¹⁴⁷ To address the concern that in the absence of smallpox vaccination campaigns monkeypox might have the potential to emerge from central Africa and occupy the niche vacated by smallpox, a WHO-sponsored active surveillance program was carried out in selected districts in the DRC from 1981 to 1986.^{153,154} This surveillance program initiated modeling of monkeypox human-to-human transmission patterns. Models predicted that the reproductive number (R_0) was less than 1 and that human-to-human transmission was at low enough levels not to present a significant public health threat. Thus, the WHO recommended against sustained vaccinia vaccination for protection against monkeypox.^{77,185}

During this period 338 cases were identified, most cases found in children (mean age, 4.4 years), leading to the hypothesis that smallpox vaccine may confer a degree of immunity in adults.^{91,122,129} Since the WHO's initial efforts at monkeypox surveillance began, outbreaks, mostly in the DRC, have been reported in the literature. Monkeypox has since supplanted smallpox as the most important orthopoxvirus affecting humans, and more attention has been directed to understanding the transmission patterns, epidemiology, and control strategies of this illness.

Epidemiology

Epidemiologic studies beginning in 1970 continue to identify outbreaks of human monkeypox, with most cases arising in the DRC. Jezek and associates^{95,96} reported disease in 338 patients and found that among patients with primary infection (i.e., cases associated with an animal source), 50% were younger than 4 years and 93% were younger than 14 years. Ninety-six percent of these children were not vaccinated against smallpox.¹⁴ Animal sources were suspected in 245 of the 338 cases, and human-to-human transmission occurred in the remaining 93 cases. Analysis of unvaccinated contacts of the patients showed a secondary attack rate of 9.3%.¹⁴ The longest chain of infection was four generations.⁹⁶ Index cases of monkeypox were usually women or children who had frequent contact with animals.^{30,41} Since initial pox lesions on the hands or arms indicative of direct inoculation were not described, infection was presumably acquired by inhaling material aerosolized

during handling or butchering of an animal. Person-to-person transmission was generally limited to family members and other close contacts, suggesting monkeypox was less transmissible than smallpox, but the small size and low population density of rural villages also may have helped limit the size of outbreaks.⁴¹

After the end of the active WHO surveillance program in 1986, only 13 cases of human monkeypox were reported until 1995, likely because political instability in the region impeded surveillance activities. In 1996 to 1997, the largest outbreak recorded to date occurred in the Kasai Oriental region of the DRC. During an initial investigation by the WHO and the Centers for Disease Control and Prevention (CDC), 92 cases were identified and a follow-up investigation suggested an additional 419 suspected cases. However, confusion with a concurrent varicella outbreak made precise estimates of the true outbreak size difficult to ascertain.^{24,77} Analysis of 320 possible and probable cases showed attack rates of 18% in susceptible individuals, 3% if vaccinated, and 26% if unvaccinated.⁷⁷ Eighty-five percent of cases occurred in patients younger than 16 years. The case-fatality rate was 1.5%, lower than the previously reported rate of 10%.²⁴ The broad case definition used for monkeypox case identification of fever and vesiculopustular rash could have included infections with varicella as well, thus artificially increasing rates of reported secondary transmission as well as artificially decreasing case-fatality rates.⁴⁶

Meyer and colleagues¹²² used viral isolation and amplification by polymerase chain reaction (PCR) to detect monkeypox virus after a 2001 outbreak in the DRC. The group found that, as in previous outbreaks, coinfection and cotransmission of varicella could have misrepresented actual cases of monkeypox. Of the seven small outbreaks, two were proved to be the result of monkeypox (16 cases, four deaths); two showed evidence of cocirculating monkeypox and varicella (seven cases, one death); two were the result of varicella-zoster virus (six cases, no deaths); and neither virus was isolated in the final outbreak. Children were the principal victims in all outbreaks.

Rimoin and colleagues¹⁵⁴ conducted active surveillance for human monkeypox in the DRC between 2005 and 2007 to assess the current burden of infection and noted a dramatic increase in monkeypox cases since the 1980s. The most heavily affected health zones showed a 20-fold increase in monkeypox activity in contrast to the 1980s, with an increase in cases from 0.72 to 14.42 per 10,000. Ninety-two percent of cases occurred in those born after smallpox vaccination ended in 1980. The study concluded that risk for monkeypox is "inversely associated with smallpox vaccination."

The burden of monkeypox disease continues to be greatest in the DRC, but outbreaks have also been reported in Sudan (now South Sudan), the Republic of Congo, and the Central African Republic in recent years. Phylogenetic and ecologic analyses indicate that monkeypox infections in South Sudan were more likely due to importation of infected animals or human-to-human transmission, rather than new zoonotic transmission in that area.^{10,42,64,111,127}

These surveillance activities have supported the three main factors determining monkeypox burden in enzootic areas: smallpox vaccination, exposure to animal reservoir species, and human-to-human transmission of disease. Smallpox vaccination officially ceased in the DRC in 1982; thus, vaccine-induced herd immunity has waned, partially contributing to increased incidence.¹⁰² Another contribution has been the change in animal contact during this time period. Monkeypox generally occurs in villages in or near tropical rainforest. Clearing of these forests as well as increased reliance on reservoir species for nutrition likely has brought humans into closer contact with reservoir species.¹⁵⁴

A noted increase in monkeypox incidence in recent years has led to concern that changes in the virus are leading to increased human-to-human transmissibility. Mathematical modeling has demonstrated that changes in viral characteristics and demographics would be required in order for endemic spread of monkeypox to occur in the human population.¹¹ While analysis of genomic variability among human monkeypox infections in the DRC showed genetic changes that may indicate active evolution toward adaptation and improved transmission between humans, no sustained transmission has yet occurred.¹⁰⁷ In fact, the longest sustained chain of human-to-human transmission has been six events.¹¹¹ The effect of increased human-to-human transmission

has not been formally investigated, but waning immunity to smallpox is thought to allow more sustained transmission of monkeypox in an increasingly unimmunized population.

Technological advances in diagnosis have made comparison of disease burden over time difficult. Thus ecological niche modeling (ENM) using human case data, satellite imaging, climatic data, and mathematical models has been employed to better define areas of potential disease transmission. ENM has predicted expansion of areas suitable for disease transmission to larger areas of the Congo Basin, which have already been involved in recent outbreaks. These areas are expected to expand in the coming century.^{53,128,175}

Two distinct clades of monkeypox virus have been identified, West African (WA) and Congo Basin (CB), with notable differences in transmissibility and clinical features. In animal models, the WA clade demonstrates less transmissibility as compared to the CB clade.⁸⁵ In addition, whereas most reports of monkeypox disease are from the DRC, these represent CB virus. There are very few reports of WA clade virus: fewer than 10 between 1970 and 2005 from Liberia, Sierra Leone, Côte d'Ivoire, and Nigeria.¹⁴⁹ Several genomic differences have been seen between the WA and CB clades that may account for differences in virulence. These include T-cell suppression and deletion of a complement control protein among WA virus linked to virulence.^{2,73,80}

Although monkeypox outbreaks in humans had been reported during the 1970s, few cases have been noted outside of the DRC.^{8,149} However, serologic evidence shows that orthopoxvirus, presumably monkeypox, may be circulating in West Africa among multiple species, including humans.^{119,150}

Only one known outbreak has occurred outside of Africa. In May of 2003, the CDC reported the first outbreak of monkeypox in humans in the Western Hemisphere among 47 patients with laboratory-confirmed or probable cases.^{25,26,27,28,150} No case fatalities and no cases of secondary transmission occurred. Fourteen cases resulted in hospitalization; two of these were severe cases in children. One girl developed encephalitis that resolved over the course of a 14-day hospitalization; a second girl developed diffuse oral and pharyngeal lesions that impaired swallowing, and she also recovered.²⁶ The outbreak was linked to the distribution of North American prairie dogs as pets that had become ill after being housed with an infected rope squirrel and an infected giant pouched rat shipped from Ghana. Patients were identified in Illinois, Indiana, Kansas, Missouri, Ohio, and Wisconsin.^{10,26,27,28,84,148} PCR analysis of tissue obtained from the prairie dogs revealed 100% similarity with the monkeypox virus strain Zaire 96-I-16 that had been isolated previously from the DRC.¹⁰³

The virus is thought to spread to humans by handling of infected animals or by direct contact with an infected animal's body fluids or lesions.¹⁰³ While it has been thought that interactions with infected wildlife would be highest risk for infection, one community study pointed to index cases as more likely to be school-aged boys, which may be related to increased susceptibility or activities of boys at this age.¹³¹ Person-to-person spread occurs by large respiratory droplets, although monkeypox transmission is much less efficient than that of smallpox.^{30,129,161} A risk factor for secondary transmission is close contact with a primary case, such as sharing food service items and sleeping quarters.¹³¹ Evidence of previous vaccination is thought to be protective, with surveillance programs estimating vaccine efficacy between 80 and 85%.^{40,59,154} Mortality rates have varied between 0 and 17% during outbreaks.^{3,11,46,62,84,91,94,96,123}

Serologic evidence suggests that many animals, including both arboreal and terrestrial rodents and nonhuman primates, can be infected with monkeypox virus, however, rope squirrels (*Funisciurus anerythrus*) are thought to be the primary host.^{46,66,84} Epidemiologic studies from the DRC have implicated squirrels living in agricultural areas as primary candidates to sustain transmission among people in nearby settlements, although no definitive host has been identified. Since 2003, there have been concerns that monkeypox virus could spread through North American rodent populations and serve as a vector for continued zoonotic exposure.⁴⁶ However, in the ensuing 14 years, this did not happen.

Clinical Features

The clinical features of human monkeypox virus infection are similar to those of smallpox, but the overall illness tends to be less severe. The

characterization of symptoms during outbreaks in Africa has been limited by poor access to medical care, retrospective identification, and civil unrest in areas of outbreaks. The outbreak reported in the Midwestern United States allowed researchers to describe clinical and laboratory parameters of disease.⁸⁴

After a 10- to 14-day period of incubation (range, 1–31 days), a 2-day prodrome of fever, malaise, and lymphadenopathy precedes the manifestation of rash.^{14,46,91} Lymphadenopathy occurs in 90% of unvaccinated individuals and is a key feature distinguishing monkeypox from smallpox because lymphadenopathy generally does not occur in smallpox. Affected lymph nodes may be unilateral or bilateral and include submandibular, cervical, postauricular, axillary, inguinal, or any combination of these locations.¹² Other signs and symptoms include chills, sweats, headache, backache, sore throat, cough, and shortness of breath.

The rash usually appears first on the face. As in smallpox, lesions develop and progress together in the same body region through the stages of macules, papules, vesicles, and pustules. Over the course of a 2- to 4-week period, the lesions progress until they finally scab over and desquamate. Most patients have discrete lesions; it is estimated that 23% have semiconfluent lesions and 7% have confluent lesions. Mucous membrane involvement and conjunctivitis are common manifestations.^{94,122} Lesions usually are found on the extremities, head, and trunk, as well as on the palms and soles.⁸² During the first week of the rash, patients are considered to be infectious.⁹³ Cases without rash have been described.⁸³ The presence of rash on the palms and soles and the stages of progression of the rash distinguish this from varicella.

Complications include secondary bacterial infection of the skin; pneumonia; vomiting, diarrhea, and dehydration; keratitis and corneal ulceration; septicemia; and encephalitis. The death rate in nonvaccinated patients was 11% in the study reported by Jezek and associates,⁹⁴ and all deaths occurred in children aged 8 years or younger, possibly reflecting protective effect in older individuals who may have received vaccinia immunization.

One case of congenital monkeypox infection has been reported.⁹⁰ The child's mother presented with clinical characteristics of monkeypox on August 12, 1983, and the child was born prematurely on September 23, 1983. At birth, the child had generalized skin lesions and died 6 weeks later of malnutrition. No data are available on the clinical course of monkeypox in patients with human immunodeficiency virus and acquired immunodeficiency syndrome (HIV/AIDS) or other immunocompromised states.

Unlike African patients, in whom more severe illness is noted, most of the patients in the United States had what was described as a mild, self-limited febrile rash illness.²⁸ The majority of patients had localized lesions associated with direct contact with infected animals, and only one patient, a child, had a generalized rash. Nevertheless, the outbreak resulted in 14 hospitalizations among the 47 cases. Differences in the severity of disease may result from differences in virulence among genetically distinct clades of monkeypox viruses: the West African monkeypox virus group and the Congo Basin isolates.¹¹⁸ Congo Basin isolates have been shown to be more virulent in nonhuman primates and, based on epidemiologic and genetic sequence analyses, are thought to be more virulent in humans as well.^{34,55,91,120,160}

Laboratory alterations noted in patients of the Midwestern US outbreak included elevated transaminases in 50% of patients, low blood urea nitrogen (61%), hypoalbuminemia (50%), leukocytosis (45%), and thrombocytopenia (35%).⁸⁴

Diagnosis

All suspect cases should be reported immediately to the local health department. Laboratory confirmation is required for establishing a definitive diagnosis. The CDC case definitions from 2004 can help guide clinicians (Box 164.1).³⁰ CDC specifies a variety of respiratory, blood, and lesion samples that may be collected from various stages of illness, as well as collection techniques at different disease stages and including respiratory samples (Table 164.2). Samples used for diagnosis include blood and cutaneous tissue from at least two scabs that have been unroofed and collected in a sterile fashion. Once lesions have been unroofed, the base of the vesicle should be swabbed with sterile cotton or polyester swab and the material applied to a clean microscope slide

BOX 164.1 Centers for Disease Control and Prevention Case Definition for Human Cases of Monkeypox (January 2004)**Suspect Case**

The patient meets one of the epidemiologic criteria and has fever or unexplained rash and two or more other signs or symptoms with onset of first sign or symptom within 21 days after the last exposure.

Probable Case

The patient meets one of the epidemiologic criteria and has fever and vesicular-pustular rash with onset of the first sign or symptom less than 21 days after the last exposure meeting epidemiologic criteria; or if rash is present but type is not described, the patient demonstrates elevated levels of IgM antibodies reactive with orthopoxvirus between at least 7 and 56 days after the rash onset.

Confirmed Case

The patient meets one of the laboratory criteria.

Clinical Criteria

Rash (macular, papular, vesicular, pustular, generalized or localized, discrete or confluent)

Fever (subjective or measured, $\geq 37.4^{\circ}\text{C}$)

Other signs and symptoms (chills and/or sweats, headache, backache, lymphadenopathy, sore throat, cough, shortness of breath)

Epidemiologic Criteria

Exposure (includes living in a household, petting or handling, or visiting a pet-holding facility such as a pet store or veterinary clinic) to an exotic or wild mammalian pet (including prairie dogs, Gambian giant rats, and rope squirrels, among others to be considered on a case-by-case basis) obtained on or after April 15, 2003, with clinical signs of illness (e.g., conjunctivitis, respiratory symptoms, and/or rash)

Exposure (as described earlier) to an exotic or wild mammalian pet (as described earlier) with or without clinical signs of illness that has been in

contact with either a mammalian pet (living in a household or originating from the same pet holding facility as another animal with monkeypox) or a human

Exposure (skin-to-skin or face-to-face contact) to a suspect, probable, or confirmed human case

Laboratory Criteria

Isolation of monkeypox virus in culture

Demonstration of monkeypox virus DNA by PCR testing of a clinical specimen

Demonstration of virus morphologically consistent with an orthopoxvirus by electron microscopy in the absence of exposure to another orthopoxvirus

Demonstration of presence of orthopoxvirus in tissue using immunohistochemical testing methods in the absence of exposure to another orthopoxvirus

Exclusion Criteria

An alternative diagnosis can explain the illness.

or

The case was reported on the basis of primary or secondary exposure to an exotic or wild mammalian pet (as described earlier) or a human subsequently determined not to have monkeypox, provided other possible epidemiologic exposure criteria are not present.

or

A patient without a rash does not develop a rash within 10 days of onset of clinical symptoms consistent with monkeypox.

The case is determined to be negative for nonvariola generic orthopoxvirus by PCR testing of a well-sampled rash lesion by the approved protocol.

The case is determined to have undetectable levels of IgM antibody 7 to 56 days after rash onset.

IgM, Immunoglobulin M; PCR, polymerase chain reaction.

Modified from Centers for Disease Control and Prevention: *Updated interim case definition for human monkeypox, Atlanta, 2004*. CDC. Available at <http://www.cdc.gov/ncidod/monkeypox/casedefinition.htm>; and Centers for Disease Control and Prevention: Update: multistate outbreak of monkeypox—Illinois, Indiana, Kansas, Missouri, Ohio, and Wisconsin, 2003. *MMWR Morb Mortal Wkly Rep*. 2003;52:561-564.

TABLE 164.2 Centers for Disease Control and Prevention Guidance for Preparation and Collection of Specimens

Disease Phase	Specimens to Collect
Prodrome	Tonsillar tissue swab Nasopharyngeal swab Acute serum and whole blood
Rash ^a	
Macules or papules	Tonsillar tissue swab Lesion biopsy Acute serum and whole blood
Vesicles or pustules	Lesion fluid, roof, or biopsy Electron microscopy grid (if supplies available) Acute serum and whole blood
Scabs or crusts	Lesion scab or crust Acute serum and whole blood
Post-rash	Convalescent serum

^aMore than one lesion should be sampled, preferably from different locations on the body and/or from different looking lesions.

From http://www.cdc.gov/poxvirus/monkeypox/clinicians/prep-collection-specimens.html#modalIdString_CDCTable_0.

and air dried. The material should be sent to the CDC or a national reference laboratory in the country of origin for diagnostic testing. Other specimens used for analysis include skin biopsy specimens, which may be indistinguishable from those of smallpox lesions, with necrosis of the stratum basale, adjacent dermal papillae, and stratum spinosum. Electron microscopy of the lesions shows abundant large, brick-shaped orthopoxvirus particles in the cytoplasm of infected epidermal cells.¹⁷² Due to limitations in specimen storage and cold chain in affected areas, lesion exudate collected on a swab or crust specimens are likely the most useful specimens.

Blood samples may be analyzed for paired acute-phase and convalescent-phase serum samples; however, serologic testing is limited because of the close antigenic relationship that exists among orthopoxviruses. More specific methods used by the CDC include cell culture or chick chorioallantoic membrane isolation, along with PCR and sequencing to differentiate monkeypox virus from other orthopoxviruses.^{41,108,116} PCR also can differentiate between Congo Basin and West African monkeypox strains.^{117,159}

Given difficulties of diagnosis in areas most affected by monkeypox, much work has been dedicated to developing rapid, specific, on-site diagnostic techniques. Dumont and colleagues demonstrated on-site deployment of dual PCR testing for monkeypox virus and varicella virus and were able to successfully identify causative viruses in three outbreaks of rashlike illness in the DRC.⁴⁹

Treatment and Prevention

In 1968, investigators reported that monkeys could be immunized against monkeypox virus using smallpox vaccine.¹²⁰ In outbreaks in the DRC described by Jezek and colleagues, as well as by more recent surveillance by Rimoin and colleagues,^{94,154} prior smallpox inoculation was found to be protective and result in a milder form of disease, often difficult to distinguish from chickenpox. Hammarlund and associates⁷² also described protective immunity to monkeypox virus in persons previously vaccinated against smallpox. Vaccine efficacy was estimated to be 85% during surveillance trials in the 1980s and more than 80% for more than 30 years during more recent surveillance.^{61,154} However, the smallpox vaccination status did not alter either the severity of illness or hospitalization rates in the Midwestern US outbreak.⁸² The CDC recommended vaccination with smallpox vaccine for those without contraindications to vaccination, including health care workers and household contacts of patients with suspected or confirmed monkeypox cases. Preexposure vaccination is preferred, but vaccination can be administered after laboratory confirmation of an infection. Vaccination should be given within 4 days but may be considered protective up to 14 days after exposure.³⁰ Currently, in the United States, vaccination is recommended for laboratory personnel working with certain orthopoxviruses and for military personnel.³³

Because of the high frequency of complications associated with administering vaccinia, work has been done to develop safer vaccines (see Chapter 163). Second-generation smallpox vaccines such as ACAM2000 have demonstrated good protection, but also have a high side-effect profile.⁷⁴ This vaccine is licensed in the United States and kept in the Strategic National Stockpile. In macaque models, third-generation vaccines using highly attenuated modified vaccinia Ankara (MVA) appear to be very efficacious against both smallpox and monkeypox with lower rates of complications than previous vaccines.¹⁷⁴ This vaccine candidate, IMVAMUNE, was shown to be safe and provide immunity in humans; as of 2010 it had been granted fast track status by the US Food and Drug Administration and is currently stockpiled for use in emergencies.³⁸ Lc16m8 is an attenuated vaccinia virus vaccine, licensed for use in Japan, which seems to exhibit a more favorable side effect profile than other vaccines and has demonstrated anti-vaccinia, -variola, and -monkeypox neutralizing antibodies.^{100,101} A variety of other vaccines intended to elicit more specific antibody responses have been studied in various primate models, and these have also shown promise.^{44,52,65,68,76,78} Some groups have also initiated work on recombinant bovine herpesvirus vaccine vectors specifically targeting monkeypox.⁶⁵

Important questions have been raised as to the risks and benefits of testing these vaccines for efficacy and vaccinating humans in monkeypox endemic areas.¹⁵² These concerns may become more relevant global public health issues should monkeypox become established in an animal reservoir outside of Africa or develop more effective human-to-human transmission.

Roess and colleagues¹⁵⁷ evaluated education-based prevention efforts in areas endemic for monkeypox; after a community intervention trial, they found improved disease recognition and transmission and risk-limitation methods in place. Until an effective and inexpensive monkeypox vaccine becomes available, this type of intervention may be the best option to provide some degree of disease prevention.¹⁵⁷

During the US outbreak, as a potential preventive measure, 28 affected residents (26 adults and two children) received a smallpox vaccine to try to prevent further transmission of monkeypox.²⁷ No data exist on the effectiveness of vaccinia immunoglobulin; however, it may be considered as a treatment for severe cases of monkeypox infection and as prophylaxis in severely immunocompromised exposed persons.⁴⁶

Of the many compounds that have been investigated as potential treatments of orthopoxvirus infections, three drugs have shown the most promise: cidofovir, brincidofovir (CMX-001), and tecovirimat. Cidofovir and brincidofovir inhibit viral DNA polymerase. Cidofovir has been shown to be active *in vitro* and *in vivo* in animal models as a potential treatment,^{3,43,144,145} but no reported data on its effectiveness for treating infected humans exists to date. However, the CDC recommends that it be considered as a treatment in severe monkeypox virus infections and in immunocompromised hosts, but should not be used as a prophylaxis because of its significant toxicities.¹⁷ Brincidofovir is

a modified form of cidofovir being developed that lacks the nephrotoxicity associated with cidofovir.⁶³ Tecovirimat (ST-246), a compound with activity against orthopoxviruses by blocking release of intracellular virus from the cell, also has shown promise in treating severe monkeypox virus infection in rodent and nonhuman primate models and may one day be approved for use in humans.^{99,162,171} It is maintained in stockpile in the United States and is available under an investigational protocol to treat orthopoxvirus infections. Mitoxantrone, a drug already FDA approved for multiple sclerosis and cancer, recently demonstrated the ability to carry some antiviral effects against monkeypox and cowpox viruses, although less effectively than cidofovir.¹ Other treatments, such as monoclonal antibodies and interferon-beta, are being investigated but remain in the preclinical phases.^{37,81,97}

Among hospitalized patients, isolation precautions should be taken because the virus may be transmitted by direct contact or large respiratory droplets that may be airborne.^{29,30} Isolation can be discontinued for patients with vesiculopustular rash after all lesions have crusted; however, contact with immunocompromised persons should be limited until all crusts have separated. For patients without rash, isolation should be continued for 7 days after the onset of fever. Asymptomatic contacts should remain under symptom surveillance for 21 days after the last exposure, and temperature should be monitored twice daily. Affected individuals should not donate any body fluids or organs while ill.³⁰

Bioterrorism Concerns

Concern over monkeypox virus as an agent of bioterrorism has been raised, but there has been no evidence to suggest that the virus becomes more severe, virulent, or easily transmissible after passages through human hosts.⁹⁶ Furthermore, evidence that monkeypox evolved independently from smallpox alleviated some fears that the virus could “evolve back” into smallpox. In addition, low rates of primary infection, limited transmissibility, and low case fatality make monkeypox an unlikely bioterrorist threat.¹³ However, some concerns remain about the potential of molecular biologic techniques to manipulate the virus genetically into a more lethal form.^{87,163}

Cowpox Virus

Cowpox disease has been recognized for hundreds of years in Europe. The infection causes ulcers on the teats of cows.⁵⁵ Those working with infected cows, including milkmaids, often developed similar ulcers on their hands and were known to be immune to smallpox. In May of 1796, this led Edward Jenner to inoculate James Phipps, an 8-year-old boy, with cowpox material obtained from a lesion on a local dairy maid.^{8,88,89,90} No infection occurred after exposing him to material from a smallpox lesion.

Cowpox is a rare illness reported throughout western Europe and northern and central Asia with the broadest host range of the poxviruses and, similar to monkeypox, likely to have wild rodents as natural reservoirs.^{5,8,15,56,105,138} With broad host and geographic range, groups have investigated varying degrees of virulence among different strains, leading to growing evidence to suggest there are at least several clades of cowpox virus, and even that these should be further divided into separate genera.^{39,51}

Baxby⁵ reported 12 human patients with illnesses caused by cowpox virus; only five were exposed to infected cows and the other seven reported no direct contact with cows. All patients, however, lived in or had visited rural areas before the onset of illness. Of the 10 patients with lesions, six had lesions on the hand only, three had lesions on the chin or face only, and one patient had lesions on both the face and hand. Most patients had local edema, lymphadenitis, and fever. Initially, lesions were confused with anthrax in two patients. With a growing portion of the population no longer immunized against smallpox, there are increasing numbers of cowpox cases reported in the literature, with a wide variety of suspected animals transmitting to humans.¹⁰⁹ Additional cases of cowpox causing mostly cutaneous infection continue to be reported from various European countries. Most identified cases resolved between 3 weeks and 6 months, but one fatality in an immunocompromised host has been reported.³⁸ Although cowpox is generally a self-limited infection, immunocompromised hosts and those with atopic skin conditions can develop more severe, even lethal, infections,

and a case of lymphadenopathy persisting for 2 years in a child was also reported.^{38,133,135} Reports of illness have followed exposure to sick animals, including cats, dogs, wild rats, voles, and other rodents. Complicated ocular infections caused by cowpox have also been reported and associated with orthopoxvirus circulating among rodents in surrounding areas.^{6,69,106,164}

As with other poxviruses, PCR has aided in specific diagnosis of the virus. Recent studies have used PCR to detect the etiologic agent of cutaneous findings: Schupp and associates¹⁶³ reported a single case of cowpox virus potentially from a cat, causing necrotic ulcers on a 12-year-old boy in Germany. The virus was isolated and detected by PCR.

Similar to monkeypox virus, several compounds have shown antiviral effects for cowpox virus in vitro or in animal models. These include cidofovir, tecovirimat, terameprocol, and mitoxantrone.^{4,140,146}

Vaccinia Virus

Vaccinia virus is the live immunizing antigen successfully used in the global program to eradicate smallpox. This orthopoxvirus is different from cowpox virus, the agent that Jenner and others used for vaccination in the early 19th century. Vaccinia virus has been used for vaccination for more than 100 years. Restriction endonuclease studies indicated that various strains of vaccinia virus from different geographic regions are similar to each other but distinctly different from cowpox virus.⁵⁵ The origin of vaccinia virus is unknown, but various hypotheses exist regarding its origin,¹⁵ including (1) evolving from variola virus through continual passage in the skin of cows or humans, (2) evolving from cowpox virus through continual passage in the skin of animals, (3) hybridization between cowpox virus and variola virus, and (4) evolving in an extinct natural animal host.

Vaccinia virus has caused outbreaks in several countries in milk herds; most commonly it has been reported in India and Brazil, with reports published since 1999. An outbreak in India was described in which infected buffaloes were thought to have had contact with vaccinated humans during smallpox eradication programs, rather than the virus being a primary buffalo pathogen.^{15,55} In several Brazilian provinces, skin lesions resembling cowpox on dairy cows and their milkers were found to be caused by a variety of vaccinia virus strains belonging to two distinct groups. During the 18th and 19th centuries, cases with vaccinia virus were thought to have evolved from repeated introduction of vaccinia.¹⁷⁷ In addition to cutaneous symptoms, patients reported fever, malaise, myalgia, headache, cough, and adenopathy.¹⁶⁸ Secondary bacterial infection of cutaneous lesions has been reported.

Because of the success of the smallpox eradication program in the United States, routine vaccinia vaccination was discontinued in 1971,^{23,158} and by 1976, the recommendation of vaccinating health care workers also was discontinued.¹⁹ However, the Advisory Committee on Immunization Practices (ACIP) continues to recommend vaccinating laboratory workers with ACAM2000 to protect them from possible infection while working with replication-competent vaccinia, recombinant vaccinia, or other orthopoxviruses capable of infecting humans (e.g., cowpox, monkeypox, variola).^{62,75,136}

In 1982, the only active licensed producer of vaccinia vaccine in the United States ceased production for general use, and distribution to civilian populations was discontinued in 1983.²² However, the CDC has continued to provide vaccinia vaccine for laboratory workers.^{20,21,124,136} In 1984, the laboratory recommendations were formally included in guidelines for biosafety in microbiologic and biomedical laboratories. This was expanded to include persons working in animal care areas where studies with orthopoxviruses were performed.¹⁶⁵

Since January 1982, smallpox vaccination has not been required for international travelers, and International Certificates of Vaccination no longer include smallpox vaccination.¹⁸⁶ Military personnel continued to be vaccinated routinely for several years after discontinuation. More recently, only selected groups of military personnel are vaccinated against smallpox; groups include those designated for military action in areas where the threat of biological warfare exists.

Recombinant Vaccinia Virus

Vaccinia virus is the prototype of the genus *Orthopoxvirus*.⁵⁵ It is a double-stranded DNA virus that has a broad host range under

experimental conditions and is rarely isolated from animals outside the laboratory. Many strains of vaccinia virus exist with various levels of virulence in humans and animals. Some examples include the Temple of Heaven and Copenhagen vaccinia strains, which are highly pathogenic in animals, and the NYCBOH strain, from which the Wyeth vaccine was derived, which has relatively low pathogenicity in animals and humans.⁵⁹

Vaccinia virus can be engineered genetically to contain and express foreign DNA without impairing the ability of the virus to replicate. Such foreign DNA can encode protein antigens that induce protection against one or more infectious agents. These recombinant vaccinia viruses created from several different strains have been engineered to express the immunizing antigens of many viruses, bacteria, parasites, and tumors of veterinary and medical importance.^{70,104,169,170,187} In the United States, recombinant viruses have been made from the NYCBOH strain or a mouse neuroadapted derivative, the WR strain. Some recombinant viruses have been made from the Copenhagen and Lister vaccinia strains, which are more pathogenic in animals than the NYCBOH strain. More recently, studies using recombinant vaccinia to vaccinate against prostate cancer, malaria, Middle East Respiratory Syndrome corona virus, tuberculosis, and HIV have used the Ankara strain.^{7,71,86,143}

Animal studies generally suggest that recombinant viruses may be no more pathogenic than the parent strain of vaccinia virus. However, no consistently reliable laboratory marker or animal test has been able to predict the attenuation of vaccinia virus or a particular recombinant virus for humans.¹⁴⁷ Laboratory-acquired infections with vaccinia or recombinant viruses have been reported^{98,139,166}; however, no surveillance system exists to monitor laboratory workers, and thus the risk for acquiring infection in persons who handle virus cultures or contaminated materials is not known.

With the initiation of human and veterinary trials using recombinant vaccines, physicians, nurses, veterinarians, and other personnel may be susceptible to both vaccinia and recombinant agents. This exposure could occur from direct contact with the recombinant virus or contaminated dressings, but the risk for transmission is unknown. To date, no reports of transmission to health care personnel from vaccine recipients have been published. When appropriate infection control precautions are observed, health care workers exposed to smaller volumes and lower titers of virus may be at less risk for acquiring infection in contrast to their laboratory counterparts.¹⁶⁷ However, because the risk for transmission exists in such persons, the ACIP suggests that all those who work or enter laboratories or animal care facilities where vaccinia, monkeypox, or cowpox viruses are being handled demonstrate evidence of vaccination. Vaccination is advised at least every 10 years for those working with vaccinia viruses. Personnel should also observe appropriate biosafety guidelines and infection control procedures.^{136,142,158,165,167,183}

Camelpox

Camelpox virus is an orthopoxvirus that is genetically the closest known virus to variola virus (smallpox virus).⁵⁰ Its disease is restricted to camels, and it is enzootic in all regions (except Australia) where camel breeding is practiced. The illness in camels is severe, with smallpox-like lesions, and has led to development of vaccines for use in camels.¹⁴¹ Human cases are occasionally reported in the literature,⁹ generally noted in animal handlers in areas where human contact with camels is common. Human illness has been mild and limited to a few cutaneous lesions.

Orf Virus

Orf virus is a member of the genus *Parapoxvirus* (see Table 58.1). Orf disease, also called *ecthyma contagiosum*,⁵⁵ is an occupationally acquired disease, with most cases occurring in adults.^{67,112} The reservoir hosts of orf virus are sheep and goats, and the virus has worldwide distribution. Human disease is characterized by single or multiple lesions that last approximately 35 to 40 days, progress through six stages, and most often are located on the hands.^{67,112} The stages include maculopapular (1–7 days), target (7–14 days), acute (14–21 days), regenerative (21–28 days), papillomatous (28–35 days), and regressive (35 to ≥40 days). Patients may have low-grade fever, but regional lymphadenitis is an uncommon finding. A range of less typical presentations due to orf virus infection has also been reported. Two patients with a widespread

papulovesicular eruption, fever, malaise, and lymphadenopathy were described.¹⁸⁴ A giant orf granuloma was described in a 12-year-old boy who lived on a farm.¹³⁷ These atypically proliferating giant orf lesions have occurred in both immunosuppressed and immunocompetent individuals. Complications after infection can occur, including erythema multiforme, bullous pemphigoid, swan-neck deformity of a finger, paresthesia, and autoimmune blistering disorders. A burn unit in Turkey reported a nosocomial outbreak involving 13 cases in which orf virus affected damaged and exposed skin.¹²³ Mortality among flocks of goats and sheep infected with orf virus can be very high, which could be economically damaging.⁷⁹

The CDC reported four unrelated cases of cutaneous, self-resolving orf virus infections in people either exposed to sheep or goats with oral lesions or who had been vaccinated recently with live orf virus vaccine. These cases occurred in New York, Illinois, California, and Tennessee, and patients' ages ranged from 11 to 51 years.³¹ Uzel and colleagues¹⁷⁹ reported nine cases of orf virus infection in Turkey related to feasts of sacrifice; adults involved in the preparation of the animals for consumption were found to be at risk. Four additional cases reported in the United States between 2009 and 2011 highlighted the potential for household exposures to the virus, including how food was prepared from infected animals.³² Orf virus infections generally do not require treatment; however, use of imiquimod in complicated cases in immunocompetent hosts⁵⁴ and in immunocompromised patients has been reported.¹¹³

Until recently, diagnosis of orf virus depended on electron microscopy or serology. In 2001, Torfason and Gunadóttir¹⁷⁶ described a PCR method to detect orf virus that helped make identification of the virus more accessible.¹⁸²

Orf virus has been shown to have immunomodulatory characteristics, antifibrotic as well as antiviral activity against recurrent genital herpes disease in guinea pigs, against hepatitis B and herpes simplex virus 1 in mice, and against hepatitis C in vitro.^{134,186} The protection in mice happens by modulating the host innate immune system, inducing phagocytosis, natural killer cell activity, and release of interferon- α , tumor necrosis factor- α , interleukin-2, and granulocyte-macrophage colony-stimulating factor. This finding may have implications for immune therapy for patients with serious infection from these viruses.¹⁸² Furthermore, the low virulence in humans and ability to repeatedly infect has made orf virus a potential backbone for delivery of oncologic treatments.¹⁵⁵

Other Parapoxviruses

Human infections with pseudocowpox virus and bovine papular stomatitis virus are considered occupational diseases. Pseudocowpox infections occur on the hands of milkers, and infections with bovine papular stomatitis virus have also been reported on the hands of veterinarians and others with close contact with cows.^{16,55,121} The initially red lesions of the pseudocowpox nodule are relatively painless, but they may be pruritic and will eventually become purple. They are firm, do not ulcerate, and typically last 4 to 6 weeks. In comparison, the lesions caused by bovine papular stomatitis virus are wartlike and typically last 3 to 4 weeks.

Additionally, reports on humans infected with other parapoxviruses from reindeer and seals are available.^{56,57,156} One report noted that in a human infection with sealpox virus, the person had orflike lesions that resolved after biopsy specimens were obtained.³⁵

Yatapoxviruses

Tanapox virus, yaba-like disease virus (YLDV), and yaba monkey tumor virus (YMTV) are three viruses found in monkeys that can cause human infection.^{41,47,48,55,92} DNA maps of tanapox virus and YLDV are extremely similar, indicating they may be the same. Tanapox in humans first was observed along the Tana River in Kenya in 1957, and outbreaks in Africa, including the DRC, have involved both children and adults.^{55,92}

The illness starts with fever, headache, backache, and mild prostration; skin lesions occur 2 to 4 days after onset. Individual lesions start as an itchy path, followed by the development of a pocklike lesion. At 7 days, lesions are approximately 10 mm in diameter with surrounding erythema. Lymphadenitis is both local and regional. The lesions ulcerate during

the second week of illness and last approximately 6 weeks. Most patients have a single lesion, but some have 2 to 10 lesions. The prognosis usually is good, although secondary bacterial infection can occur.

Two cases of tanapox were reported in the United States. The first case was a 51-year-old man with papular lesions with general malaise after visiting Tanzania and being exposed to a cat.¹⁷³ A second case occurred in a 21-year-old female student from New Hampshire, who developed fever, headaches, malaise, and several papules after being exposed to chimpanzees in the DRC.³⁶ The symptoms of both patients were diagnosed using PCR techniques and resolved spontaneously. As international travel increases, more case reports of such poxvirus illnesses may surface. PCR techniques to diagnose such infections quickly have been developed,^{45,173,188} and these methods will assist in rapid diagnosis of poxvirus illnesses that may be confused with more serious illnesses such as smallpox and monkeypox. Of interest, tanapox virus has been recently been studied in human cancer cell lines in hope of developing an oncolytic viral vaccine to be used therapeutically in a variety of human cancers with minimal side effects.¹¹⁴

YMTV was isolated from tumors in monkeys in Nigeria, and animal handlers in primate centers in the United States have become ill as a result of this virus. Human infections have not been identified in the field in Africa. YMTV produces epidermal histiocytomas, tumorlike masses of histiocytic polygonal mononuclear cell infiltrates that may advance to suppurative inflammation.⁴¹

Molluscum Contagiosum Virus

In contrast to the other zoonotic poxviruses discussed in this chapter, *molluscum contagiosum* virus is a human virus that is a common cause of human skin lesions⁵⁵ (see Chapter 60B and Table 58.1). The virus has not been grown in cell culture as yet, but has been extracted from human lesions, and it does not cause infection in experimental animals. Analysis of viral DNA from lesions in geographically different patients indicates existence of two major subtypes and a third, rare subtype. The clinical aspects of molluscum contagiosum virus infection are presented in Chapter 60B.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Because all but two viruses presented in this chapter are zoonotic agents, careful attention must be given to geographic location and animal exposure. All diseases described here are characterized by local lesions, which easily can be collected for direct identification. All poxviruses can be identified by examination of material from lesions by electron microscopy and by PCR.¹³⁰ All viruses except molluscum contagiosum virus grow in one or more tissue culture systems, the chorioallantoic membrane of embryonated eggs, or both. Unusual agents should be referred to specific reference laboratories for species identification.

Mimiviruses

Ramya Ramraj • Gail D. Harrison

In 1992, while investigating the source of an outbreak of community-acquired pneumonia in a hospital in Bradford, in northern England, investigators discovered a bizarre microorganism.^{13,14} The microorganism, resembling a small gram-positive coccus, was found inside a free-living amoeba in a water cooling tower. Researchers initially thought it was a bacterium, but subsequent analysis demonstrated a giant double-stranded DNA virus, and it was reported in 2003 to be a giant virus of amoeba called *Acanthamoeba polyphaga mimivirus* (APMV), more commonly known now as *Mimivirus*. Originally named mimivirus or “mimicking microbe” because it resembled bacteria in Gram-stained smears, it now is designated officially as a quasi-autonomous virus,

Acanthamoeba polyphaga mimivirus. It is a member of the order Megaviridae, family Mimiviridae (nucleocytoplasmic large DNA viruses), and genus *Mimivirus*, defining a new fourth domain of life containing these nucleocytoplasmic large DNA viruses.^{4-6,15} There is now a closely related *Mamavirus* comparable to the complex virus *Mimivirus*, so named because it appears larger than *Mimivirus*, but with similar characteristics.

There are now four new proposed families of giant viruses that have been isolated: Pandoravirus, Pithovirus, Faustovirus, and Mollivirus. The role of these giant viruses in human disease is still unknown. The role of the megavirome in human disease is still emerging.

STRUCTURE AND PROPERTIES

A. polyphaga mimivirus is a giant, double-stranded, icosahedral DNA virus.^{3,4} With a diameter of approximately 650 nm, *Mimivirus* is the fourth largest virus known to date. *Mimivirus* morphologically resembles nucleocytoplasmic large DNA viruses (NCLDVs), such as the iridovirus, asfarvirus, and phycodnavirus.^{10,30} However, evolutionary dissimilarities define a new family, the Mimiviridae.¹³ *Mimivirus* comprises a central dense core that is surrounded by two lipid membrane layers inside a capsid protein shell covered by fibrils. The 1.2-Mb genome sequence^{19,22,25} is complex and possesses genes that are shared by the NCLDV families as well as several that have not been identified previously in viruses. The origins and the various processes¹ involved in shaping gene content of *Mimivirus* are not entirely clear at this time.^{13,19} It appears that these giant virus particles contain mRNA and more than 100 proteins; they have gene repertoires that are broad and encode for translation components. The mimiviruses also are infected by virophages, including the satellite virus Sputnik virophage, a 740-Å diameter satellite virus with an icosahedral capsid and a lipid membrane inside a protein shell that infects mamaviruses. Sputnik is thought to have been derived from other viruses, prior to its association with the giant *Mimivirus*.^{6,8,28}

The virus can survive on inanimate surfaces for at least 30 days, is resistant to alcohol-based biocidal agents, but is inactivated by free chlorine and glutaraldehyde.^{3,10}

VIRAL REPLICATION

In *A. polyphaga*, the replication cycle of *Mimivirus* starts with entry of the virus by phagocytosis, followed by a 4-hour eclipse phase inside the nucleus,¹³ and then the formation of the “virus factory” in the cytoplasmic space,²⁹ ending with cell lysis and virus release 24 hours after infection (Fig. 165.1). The virus factory,²⁰ where virus replication and assembly occur, is the major site of production of *Mimivirus* DNA and induces profound alteration of the infected cell structure, such as by recruitment of organelles and organization of cellular compartments. Very specific mechanisms and complex interactions between viral and cellular factors that are not entirely clear at this time must be involved to build this remarkably large and efficient virus factory, which can generate this sophisticated microorganism rapidly.²⁹ The Sputnik virophage infects the giant viruses of the genus *Mimivirus*.⁸

ANIMAL SUSCEPTIBILITY

An experimental model of infection was developed to establish a possible role of *Mimivirus* as a human pathogen. Autopsy specimens of laboratory mice that were inoculated intracardially with infecting units of *Mimivirus* revealed histopathologic evidence of pneumonia, and mimiviruses were reisolated from samples from the lung.¹² Inoculation of human

FIG. 165.1 Schematic representation of the *Acanthamoeba polyphaga mimivirus* replication cycle. 1, *Mimivirus* entry through a phagocytic vacuole. 2, Fusion of phagocytic vacuoles and delivery of *Mimivirus* genetic material into the cell cytoplasm (3). 3, *Mimivirus* DNA entry into the host nucleus, where the first round of DNA replication could begin (4). 5, At 3 hours after infection, *Mimivirus* DNA comes from the host nucleus to form the virus factory (VF) replication center. 6, At 5 hours after infection, the VF size shows a 50% increase, and viral proteins begin to be detected; proviral capsid assembly and viral capsids budding from the VF central core can be observed. 7, Empty or DNA-filled capsids accumulate near the central core, resulting in a growing VF with viral particles free in the cytoplasm. 8, Complete viral capsids surrounded by fibrils may be released through cell lysis. (From Suzan-Monti M, La Scola B, Barrassi L, et al. Ultrastructural characterization of the giant volcano-like virus factory of *Acanthamoeba polyphaga mimivirus*. *PLoS One*. 2007;2:e328.)

macrophages with mimiviruses showed evidence of infection, although no evidence of a lytic cycle was observed.²³ Efforts to induce infection in other cell lines were futile, and the target cell in mice remains to be identified.

MIMIVIRUS INFECTION IN HUMANS

In December 2004, a laboratory technician in France developed subacute pneumonia with dry cough, fever, and chest pain.²⁴ This technician was in charge of performing *Mimivirus* serologic testing and Western blot analysis and thus had handled relatively large amounts of *Mimivirus* antigens. Radiographic examination of his chest revealed bilateral basilar infiltrates (Fig. 165.2). The illness did not respond to amoxicillin-clavulanate treatment prescribed on day 15 after the onset of symptoms, but after an additional 2 weeks, the illness resolved, and the technician made a full recovery. Serum samples screened against pneumonia agents showed seroconversion (<1:50 to 1:3200) only for *Mimivirus*, which was confirmed by testing with two-dimensional Western blotting against 23 identified proteins of *Mimivirus*. *Mimivirus* has also been isolated from a patient with pneumonia.²⁶

Little is known about the host defense relationship of *Mimivirus* with humans. However, studies have shown that it is recognized by the human immune system, and it is able to interfere with the human type 1 interferon system.²⁷

Prevalence of Antibodies to *Mimivirus* in Patients With Pneumonia

Three early studies investigated the prevalence of antibodies to *Mimivirus* in specific human populations.²³ The first study tested serum samples obtained from 376 Canadian patients with community-acquired pneumonia and from 511 healthy subjects. A total of 9.66% of patients with pneumonia had antibodies to *Mimivirus*, compared with 2.3% of control subjects.¹⁸ Patients with pneumonia who had antibodies to *Mimivirus* were more likely to be hospitalized from a nursing home and to be rehospitalized after discharge.¹⁶ The second study included

FIG. 165.2 Chest radiograph of a laboratory technician who was infected with *Mimivirus*, with bilateral basilar infiltrates evident. (From Raoult D, La Scola B, Birtles R, et al. The discovery and characterization of *Mimivirus*, the largest known virus and putative pneumonia agent. *Clin Infect Dis*. 2007;45:95–102.)

26 patients from Marseille, France, who acquired pneumonia while in an intensive care unit and 50 control serum samples (from blood donors). Antibodies to *Mimivirus* were detected in samples obtained from five patients but in none of the control samples.¹⁶ The third serosurvey involved 157 patients in intensive care units who had pneumonia. Serum specimens obtained from these patients were tested against a panel of antigens from “conventional” pneumonia agents as well as ameba-associated microorganisms, including *Mimivirus*.² Evidence of infection with conventional pathogens was found in 28 cases and with ameba-associated pathogens in 18 cases. In the group infected by ameba-associated pathogens, more patients had seroconversion to *Mimivirus* than to any other pathogen (five cases), and seroconversion was more common among patients with ventilator-associated pneumonia than among those with community-acquired pneumonia (31.6% and 10.5% of patients, respectively). Additional serologic studies have shown an association of *Mimivirus* seropositivity and increased duration of mechanical ventilation and prolonged stay in the intensive care unit in adult patients.³²

However, studies that have used molecular detection techniques of reverse transcription–polymerase chain reaction (RT-PCR) have not detected *Mimivirus* DNA in respiratory secretions of hospitalized adult and pediatric patients with pneumonia.^{7,17,32,33} Taken together, these studies reveal a significant rate of seroconversion and seropositivity in hospitalized patients with either community-acquired pneumonia or hospital-acquired pneumonia, but direct detection of the pathogen in clinical respiratory secretions has not been confirmed.²³

The first isolation of *Mimivirus* from a patient with pneumonia has been reported.²⁶

Mimivirus has been detected by molecular and virologic methods to be present on inanimate surfaces in hospital settings, especially in respiratory-isolation units, suggesting that mimiviruses may play a potential role nosocomial or health care–associated infections.⁹ However, mimiviruses have not been found to be a cause of ventilatory-associated pneumonia in hospitalized patients in intensive care units.³¹

DIAGNOSTIC METHODS

Diagnostic strategies include collection of nasal wash specimens, bronchoalveolar lavage (BAL) fluid, and serologic samples. Serologic testing includes immunofluorescence assay of samples of acute-phase and convalescent-phase serum for antibodies to proteins specific for *Mimivirus*.² However, one study using immunoproteomics showed cross reaction between *Mimivirus* and *Francisella tularensis*, suggesting caution in interpretation of results when only serologic methods are employed to diagnose *Mimivirus* infection or to determine associations of *Mimivirus* and pneumonia.²¹

Mimivirus also can be cultivated by coculture with amoeba.¹¹ It also can be detected in DNA extracted (QIAamp tissue kit; Qiagen) from BAL samples amplified by a PCR assay.² However, real-time PCR methods have failed to consistently detect *Mimivirus* in clinical respiratory secretions obtained from patients with pneumonia. The strongest evidence of infection includes a combination of positive BAL culture, positive PCR assays, and fourfold increase in antibody titer between acute-phase and convalescent-phase serum samples or significant seroconversion for *Mimivirus*.²

MIMIVIRUS AS AN EMERGING PATHOGEN

Evidence indicates that *Mimivirus* is a new human pathogen that causes pneumonia.³ However, *Mimivirus* does not replicate efficiently in coculture with any of the mammalian cells tested to date, and serologic cross reactions among pathogens are observed commonly. Isolation of the virus or DNA detection by RT-PCR from respiratory secretions of patients with pneumonia has not consistently confirmed the presence of the pathogen directly in clinical samples from adults and children.^{16,35}

Mimivirus infection in hospitalized children with pneumonia has not been confirmed.³⁵ However, *Mimivirus* has been isolated from a patient with pneumonia on at least one occasion and has been detected in the blood and lymph node of a child.²⁶

SUBSECTION I RNA—Picornaviridae

Enteroviruses, Parechoviruses, and Saffold Viruses

166

James D. Cherry • Paul Krogstad

Enteroviruses (EVs), parechoviruses (PeVs), and Saffold viruses (SAFVs) are members of three distinct genera of the Picornaviridae family of small RNA viruses. Although these viruses have clear differences in their structural features and molecular biology, they have overlapping clinical features and epidemiology and are therefore discussed together in this chapter.

HISTORY

Poliomyelitis, the first enteroviral disease to be recognized and the most important one, has a long history.⁸⁹⁴ The earliest record is an Egyptian stele of the 18th dynasty (1403–1365 BCE) that shows a young man with a withered, shortened leg, the characteristic deformity of paralytic poliomyelitis.^{503,768} Michael Underwood,¹¹¹¹ a London pediatrician, published the first medical description in 1789 in *A Treatise on Diseases of Children*. During the 19th century, many reports appeared in Europe and the United States describing small clusters of cases of “infantile paralysis.” These investigators were puzzled about the nature of the affliction; not until the 1860s and 1870s was the spinal cord firmly established as the seat of the pathologic process. The contagious nature of poliomyelitis was not appreciated until the late 19th century. Medin, a Swedish pediatrician, was the first to describe the epidemic nature of poliomyelitis (1890), and his pupil Wickman¹¹⁶³ worked out the basic principles of the epidemiology.

The virus was isolated first in monkeys by Landsteiner and Popper⁶⁶⁹ in 1908. The availability of a laboratory animal assay system opened many avenues of research that in the ensuing decades led to the demonstration that an unrecognized intestinal infection was the usual manifestation and the finding that paralytic disease was a relatively uncommon event.

Coxsackieviruses and echoviruses have had a shorter history. Epidemic pleurodynia was described clinically in 1735 by Hannaeus⁴⁵⁵ more than 200 years before the coxsackieviral origin of this disease was discovered. In 1948, Dalldorf and Sickles²⁸⁰ first reported the isolation of a coxsackievirus after inoculation of suckling mice.

In 1949, Enders and associates³³³ described the growth of poliovirus 2 in tissue culture, and their techniques paved the way for recovery of a large number of other cytopathic viruses. Most of these “new” viruses failed to produce illness in laboratory animals. Because the relationships of many of these newly recovered agents with human disease were unknown, these agents were called *orphan viruses*.⁷⁶⁷ Later, several agents

were grouped together and were called enteric cytopathogenic human orphan viruses, or echoviruses. Two such viruses identified in 1956 by Wigand and Sabin in studies of summer diarrhea were originally classified as echoviruses 22 and 23 but were reclassified into a new genus (*Parechovirus*) in the late 1990s because of features of their structure and replication that distinguish them from EVs.¹⁰⁴⁵ Similarly, stool cultures of a child evaluated in 1981 for prolonged fever revealed a novel virus that became the first recognized SAFV when molecular methods revealed similarities to known members of the cardiovirus genus of the picornavirus family.^{580,1218}

Inactivated and live-attenuated poliovirus vaccines became available in the late 1950s and early 1960s, and the most notable advance since the late 1980s has been a dramatic reduction in worldwide poliomyelitis as a result of the global immunization initiative.^{249,527,881,1080} The last case of confirmed paralytic poliomyelitis in the Western Hemisphere caused by a wild-type virus strain occurred in 1991.⁹⁵³

Since the 1950s, pandemics of specific nonpolio EV have occurred. These were caused by echovirus 9 in the 1950s, coxsackievirus A16 in the 1960s, and, more recently, EVs 71 and D68. Interestingly, during the period of almost universal use of oral poliovirus vaccines (OPVs) between the 1960s and 2000 there were no nonpolio virus pandemics. In the present era with the switch from OPV to inactivated poliovirus vaccines (IPV) both EV 71 and EV D68 have emerged in much of the developed world.

THE VIRUSES

Classification

EVs, PeVs, and SAFVs are RNA viruses belonging to the family Picornaviridae (*pico*, “small”).^{*} These viruses are grouped together because they share certain physical, biochemical, and molecular properties. In electron micrographs, the viruses are seen as 30-nm particles that consist of naked (nonenveloped) protein capsids, constituting approximately 70% to 75% of the mass of particles that contain the genomic RNA.

To bring order to the growing list of poliovirus-like agents, coxsackieviruses, echoviruses, and polioviruses first were categorized together and named in 1957 by a committee sponsored by the National Foundation for Infantile Paralysis.⁷⁷⁴ The human alimentary tract was thought to

TABLE 166.1 Original Classification of Human Enteroviruses: Animal and Tissue Culture Spectrum^a

Virus	Antigenic Types ^b	CYTOPATHIC EFFECT		ILLNESS AND PATHOLOGY	
		Monkey Kidney Tissue Culture	Human Tissue Culture	Suckling Mouse	Monkey
Polioviruses	1–3	+	+	–	+
Coxsackieviruses A	1–24 ^c	–	–	+	–
Coxsackieviruses B	1–6	+	+	+	–
Echoviruses	1–34 ^d	+	±	–	–

^aMany enterovirus strains have been isolated that do not conform to these categories, thus leading to the revised classification scheme shown in Table 166.2.
^bNew types, beginning with type 68, were initially assigned enterovirus type numbers instead of coxsackievirus or echovirus numbers. Types 68 through 71 were identified before the strategy for taxonomy was changed, as described in the text.
^cCoxsackievirus A23 was found to be the same as echovirus 9.
^dEchovirus 10 was reclassified as a reovirus; echoviruses 22 and 23 were made the first members of the *Parechovirus* genus within the picornavirus family, and echovirus 28 was reclassified as a rhinovirus.
+, Present; –, absent; ±, variably present.

be the natural habitat of these agents, and the term *enterovirus* was coined. They were originally distributed into four groups (Table 166.1) on the basis of their different effects in tissue culture and pattern of disease in experimentally infected animals: polioviruses (causal agents of poliomyelitis in humans and nonhuman primates), coxsackieviruses A (associated with herpangina, human central nervous system [CNS] disease, and flaccid paralysis in suckling mice), group B coxsackieviruses (human CNS and cardiac disease, spastic paralysis in mice), and the echoviruses (nonpathogenic in mice and not linked to human disease at first). Although this scheme was useful initially, many strains were isolated subsequently that do not conform to such rigid specificities. For example, several coxsackievirus A strains replicate and have a cytopathic effect in monkey kidney tissue cultures, and some echovirus strains cause paralysis in mice.

For this reason, and to simplify the nomenclature, EVs subsequently were assigned sequential numbers. Following this convention, the prototype EV strains Fermon, Toluca-1, J 670/71, and BrCr (identified between 1959 and 1973) were designated EV 68 through EV 71, respectively. Additional EVs continued to be identified that could not be identified using antisera specific for the classic serotypes. More than 50 distinct additional EVs have been identified by culture and molecular detection methods, although not all have not been linked to human disease.

Since the late 1990s, genetic, biologic, and molecular properties have been used to revise picornavirus taxonomy. Determining the nucleotide sequence encoding the viral VP1 capsid protein plays a major role in this approach and predictably identifies viruses originally classified by serologic means, thus leading to the term *molecular serotyping*.^{860,861,915,923} This phylogenetic technique formed the basis for taxonomic reorganization of the EVs known to infect humans into four alphabetically designated species (EV-A, EV-B, EV-C, and EV-D) (Table 166.2). The three polioviruses (PV1–PV3) are members of EV-C, in view of their close molecular relationship with other members of the species.¹²³

As noted previously, two of the original echoviruses (echoviruses 22 and 23) were found to have genomic and proteomic differences from the other early “enteroviruses” and were reclassified as first members of the new genus *Parechovirus* as *Human Parechovirus* (HPeV) types 1 and 2.^{927,1045,1046} Fourteen additional types of human HPeV have now been identified. Similarly, hepatitis A virus was initially assigned the designation EV 72, but it was reclassified as the prototype of the *Hepatitis virus* genus within the picornavirus family because of marked genetic and biologic distinctions from all other picornaviruses.

The *Cardiovirus* genus of the Picornaviridae has been augmented by identification of the SAFVs. Beginning with a strain isolated in 1981 and characterized in 2007, 11 genetically distinct SAFVs have been identified since 2007 and grouped into the *Cardiovirus* B species.⁵⁸⁰

The application of molecular phylogenetic approaches has also revealed that recombination between circulating picornaviruses is a frequent event and is likely to increase the genetic diversity of EVs,

TABLE 166.2 Genomic Classification of Enteroviruses^a

Species Designation	Types
Enterovirus A (EV-A)	Coxsackievirus A2–8, 10, 12, 14, 16
	Enterovirus A71, A76, A89, A90, A91, A114, A119
Enterovirus B (EV-B)	Coxsackievirus A9
	Coxsackievirus B 1–6
	Echovirus 1–9, 11–21, 24–27, 29–33
	Enterovirus B69, B73–75, B77–88, B93, B97, B98, B100, B101, B106, B107
Enterovirus C (EV-C)	Poliovirus 1–3
	Coxsackievirus A 1, 11, 13, 17, 19–22, 24
	Enterovirus C95, C96, C99, C102, C104, C105, C109, C113, C116–C118
Enterovirus D (EV-D)	Enterovirus D68, D70, D94, D111

^aCoxsackievirus A15 has been reclassified as a strain of coxsackievirus A11, and coxsackievirus A18 has been reclassified as a strain of coxsackievirus A13. Echovirus 34 has been recognized as a variant of coxsackievirus A24.

cardioviruses, and PeVs.* This propensity for recombination has played a role in more recent outbreaks of paralytic diseases involving vaccine-derived strains of poliovirus.⁶¹⁵

Morphology and Replication

EVs, PeVs, and SAFVs have single-stranded, positive-sense RNA genomes that are 7.4 to 8 kb in length.⁹¹⁶ For all three, the genome consists of a 5′ noncoding region followed by a single long open-reading frame, a short 3′ noncoding region, and a poly-A tail. The 5′ noncoding region contains a 450-nucleotide internal ribosome entry site that recruits the translational machinery to an initiation site approximately 740 nucleotides downstream from the 5′ terminus of the viral RNA. The 3′ noncoding region folds into a highly conserved structure that is required for initiation of the synthesis of a minus-sense viral RNA that in turn is the template for the message-sense genomic RNA. This genome is packaged into capsids that exhibit icosahedral symmetry with 20 triangular faces and 12 vertices.

Replication of EVs begins with the adsorption of virions to cell surface receptors; most of those known are integrins or immunoglobulin-like

TABLE 166.3 Cellular Receptors and Cofactors for Infection of Representative Enteroviruses

Virus	HEV Species	Receptor	Cofactor for Infection ^a
Enterovirus 71	EV-A	PSGL-1, SCARB2	
Coxsackieviruses B1–6	EV-B	CAR	Some group B coxsackieviruses may use CD55 (DAF) or heparan for attachment
Echovirus 9	EV-B	$\alpha_5\beta_3$ integrin (vitronectin receptor)	MAP-70
Echoviruses 1, 8	EV-B	VLA-2 ($\alpha_2\beta_1$ integrin)	Heparan sulfate
Coxsackieviruses A13, 17, 20, 21, 24	EV-C	ICAM-1	
Polioviruses 1–3	EV-C	CD155(PVR)	
Enterovirus 70	EV-D	CD55 (DAF)	

CAR, Coxsackie and adenovirus receptor; DAF, decay-accelerating factor; HEV, human enterovirus; ICAM-1, intercellular adhesion molecule 1; MAP-70, microtubule-associated protein 70; PSGL-1, P-selectin glycoprotein ligand 1; Pvr, poliovirus receptor; SCARB2, scavenger receptor class B member 2; VLA-2, a human integrin.

^aThe cofactors generally facilitate adhesion to cells, but their sole expression is insufficient to permit infection to occur.

proteins (Table 166.3). The virions penetrate the surface of the cell and undergo conformational changes that release the viral genome, which functions as the messenger RNA that encodes viral polypeptide.^{693,1014}

This polypeptide contains three domains, P1 to P3, which are cleaved into three or four proteins each. The P1 region is liberated from the polypeptide by the viral 2A protein, a chymotrypsin-like protease. P1 initially is split into three proteins, VP0, VP1, and VP3, by the viral 3C protease. VP0 is subsequently processed during virion maturation into two smaller proteins, VP4 and VP2. Portions of VP1, VP2, and VP3 are exposed at the surface of the virion, whereas VP4 is entirely internal. VP1, VP2, and VP3 have no sequence homology but share the same topology.⁹²⁷ Specifically, they form an eight-stranded antiparallel β -barrel that is wedge shaped and comprises two antiparallel β -sheets. The amino acid sequences in the loops that connect the β -strands and the N- and C-terminal sequences that extend from the β -barrel domain of VP1, VP2, and VP3 give each EV its distinct antigenicity. The replication of EVs occurs in the cytoplasm in membrane-associated replication complexes and is completed rapidly (5–10 hours). Studies of polioviruses and coxsackieviruses have shown that enteroviral replication is associated with disruption of cellular protein secretion, and host-cell protein synthesis is suppressed because of cleavage of human eukaryotic translation initiation factor 4G (eIF4G) by enteroviral 2A proteases, which abrogates cap-dependent translation. The coxsackievirus 2A protein also cleaves dystrophin, a cytoskeletal protein; this activity has been hypothesized to play a role in damage to the myocardium.^{52,301}

The PeVs replicate in a similar fashion.⁶⁵² Integrins ($\alpha_5\beta_3$ and perhaps $\alpha_5\beta_1$ and $\alpha_5\beta_6$) are used as receptors, and replication occurs in cytoplasmic structures.⁷⁷⁶ However, the P1 portion of the viral polypeptide is processed into only three capsid proteins, and only one protease has been identified in the PeVs. In addition, PeV replication occurs in small, discrete foci in the cytoplasm, rather than in large accumulations of membranous vesicles like the EVs. Moreover, transcription and translation do not appear to be disrupted by the PeVs, thus perhaps explaining their relatively mild and delayed cytopathic effect when they are grown in tissue culture.¹⁰⁴⁵

The replication of the Saffold cardioviruses has not been specifically examined, but genetic similarities to Theiler murine encephalomyelitis virus (TMEV) and other murine cardioviruses suggest that they possess a single protease related to the 3C protease of other picornaviruses.⁴⁸⁸ The SAFV genome also appears to encode a leader (L) protein at the amino terminus of the viral polypeptide. The L proteins of TMEV and encephalomyocarditis viruses are thought to modulate viral translation, innate immune responses, and cellular apoptosis.⁴⁸⁸

Replication Characteristics and Host Systems

EVs and PeVs are relatively stable viruses in that they retain activity for several days at room temperature and can be stored indefinitely at ordinary freezer temperatures (-20°C [-4°F]). They are inactivated quickly by heat ($>56^{\circ}\text{C}$ [132.8°F]), formaldehyde, chlorination, and ultraviolet light, but they are refractory to ether, ethanol, and isopropanol.^{771,775,880,960}

Enteroviral strains grow rapidly when adapted to susceptible host systems and cause cytopathologic features in 2 to 7 days. The typical

tissue culture cytopathic effect is shown in Fig. 166.1; characteristic pathologic findings in mice are shown in Figs. 166.2 and 166.3. Final titers of virus recovered in the laboratory vary markedly among different viral strains and the host system used; typically, concentrations of 10^4 to 10^8 infectious units/mL tissue culture fluid or tissue homogenate are obtained. Unadapted viral strains frequently require long periods of incubation. In both tissue culture and suckling mice, evidence of growth usually is visible. Blind passage occasionally is necessary for the cytopathologic features to become apparent.

Although many different primary and secondary tissue culture systems support the growth of various EVs, primary rhesus monkey kidney cultures generally are accepted to have the most inclusive spectrum.^{126,1053} Other simian kidney tissue cultures, however, also have the same broad spectrum. Tissue cultures of human origin have a more limited spectrum, but several echovirus types have shown more consistent primary isolation in human than in monkey kidney culture. A satisfactory system for the primary recovery of EVs from clinical specimens would include the following: primary rhesus, cynomolgus, or African green monkey kidney; a diploid, human embryonic lung fibroblast cell strain; rhabdomyosarcoma cell line tissue cultures; and intraperitoneal and intracerebral inoculation of suckling mice younger than 24 hours.^{76,464,478,771,775,960,1053}

Antigenic Characteristics

Although some minor cross-reactions exist among several coxsackievirus and echovirus types, common group antigens of diagnostic importance have not been defined well.^{770,771,768,775,880} Heat treatment of virions and the use of synthetic peptides have produced antigens with broad enteroviral reactivity.^{1082,1083} These antigens have been used in enzyme-linked immunosorbent assay and complement fixation tests to determine immunoglobulin (Ig) G and IgM enteroviral antibodies and for antigen detection. In one study, Terletskaia-Ladwig and colleagues¹⁰⁸² reported the identification of patients infected with EVs by the use of an IgM enzyme immunoassay. This test used heat-treated coxsackievirus B5 and echovirus 9 as antigens, and it identified patients infected with echoviruses 4, 11, and 30. The sensitivity of the test was 35%. In another study involving heat-treated virus or synthetic peptides, the respective sensitivities were 67% and 62%.¹⁰⁸³ However, both tests lacked specificity. Intratypic strain differences are common findings, and some strains (prime strains) are neutralized poorly by antisera to prototype viruses. In animals, however, these prime strains induce antibodies that neutralize the specific prototype viruses.

The identification of polioviral, coxsackieviral, and echoviral types by neutralization in suckling mice or tissue culture with antiserum pools is relatively well defined. Neutralization is induced by the epitopes on structural proteins VP1, VP2, and VP3; in particular, several epitopes are clustered on VP1. Prime strains do cause diagnostic difficulty because frequently they are not neutralized by the reference antisera, a particular problem with echoviruses 4, 9, and 11 and EV 71. If these types are suspected, in some instances this problem can be overcome by using antisera in less diluted concentrations or antisera prepared against several different strains of problem viruses. Kubo and associates⁶⁵⁵ were able to type enteroviral isolates not identified through neutralization by

FIG. 166.1 Fetal rhesus monkey kidney tissue culture (HL-8). (A) Uninoculated tissue culture. (B) Echovirus 11 cytopathic effect. (From Cherry JD. Enteroviruses. In: Remington JS, Klein JO, eds. *Infectious Diseases of the Fetus and Newborn Infant*. Philadelphia, PA: WB Saunders; 1976.)

nucleotide sequence analysis of the VP4 gene. These investigators specifically identified prime strains of echovirus 18 and EV 71. Sequence analysis of the VP1 gene also is useful for typing enteroviral prime strains not identified by neutralization.⁸⁵⁰

Host Range

Humans are the only natural hosts of polioviruses, coxsackieviruses, and echoviruses.^{1,279,399,623,767,1011,1158,1160} However, EVs have been recovered in nature from sewage, flies, swine, dogs, a calf, a budgerigar, a fox, mussels, monkeys, and oysters.²⁰⁰ In addition, serologic evidence of infection with EVs similar to human strains has been noted in chimpanzees, cattle, rabbits, a fox, a chipmunk, and a marmot.²⁰⁰ Various

EVs that are distinct from the human EVs have been isolated from nonhuman primates.⁸⁶² Contamination of shellfish also is interesting because, in addition to a possible role in human infection, shellfish offer a source of enteroviral storage during periods of cold weather.²⁰⁰ Contaminated food is another possible source of human infection.²⁰⁰

EPIDEMIOLOGY

Transmission

The spread of human EVs, PeVs, and also presumably SAVFs, is from person to person by the fecal-oral and possibly the oral-oral (respiratory spread) route. Swimming and wading pools may serve as a means of

FIG. 166.3 Suckling mouse skeletal muscle. (A) Normal suckling mouse skeletal muscle. (B) Skeletal muscle of a mouse infected with coxsackievirus A16. (From Cherry JD. Enteroviruses. In: Remington JS, Klein JO, eds. *Infectious Diseases of the Fetus and Newborn Infant*. Philadelphia, PA: WB Saunders; 1976.)

spread of EVs during the summer.⁶¹¹ Oral-oral transmission by way of the contaminated hands of health care personnel and transmission by fomites were documented in a long-term care pediatric ward.⁵⁷² EVs have been recovered from trapped flies, and such carriage probably contributes to the spread of human infection, particularly in lower socioeconomic populations with poor sanitation facilities.²⁰⁰ Between 1972 and 2004, Sinclair and colleagues¹⁰³² noted 13 outbreaks of EV disease related to swimming in lakes, pools, or the ocean. One noteworthy point-source outbreak occurred in a group of travelers to Mexico who swam in contaminated seawater.⁷¹ Of 29 travelers (25 teenagers and four adults) 21 became ill; four had echovirus 30 infection, 11 had coxsackievirus A1 infection, and four had both viruses isolated.

Children comprise the main susceptible cohort; they are immunologically susceptible, and their unhygienic habits facilitate the spread of infection. Spread is from child to child (from feces to skin to mouth) and then within family groups. Recovery of EVs is related inversely to age, but the prevalence of specific antibodies is related directly to age. The incidence of infection and the prevalence of antibodies do not differ between boys and girls.

Geographic Distribution and Season

EVs, PeVs, and SAFVs have worldwide distribution.^{200,362,381,399,1218} Neutralizing antibodies for specific viral types have been noted in serologic surveys throughout the world, and most strains have been recovered in global isolation studies. In any given area, frequent fluctuations occur in predominant types. Epidemics probably depend on newly susceptible individuals in the population rather than on reinfection. Epidemics may be localized and sporadic, and they may vary in origin from place to place in the same year. Pandemic waves of infection also occur.

In temperate climates enteroviral infections occur primarily in the summer and fall, but in the tropics they are prevalent all year.^{200,399,770} A basic concept in understanding the epidemiology of these illnesses concerns the far greater frequency of unrecognized infection than clinical disease, as illustrated by poliomyelitis, which remained an epidemiologic mystery until researchers appreciated that unrecognized infections were the main source of contagion. Serologic surveys were instrumental in elucidating the problem; in populations living in conditions of poor sanitation and hygiene, epidemics did not occur, but wide dissemination of polioviruses was confirmed by demonstrating the presence of specific

antibodies to all three types in almost 100% of children by the time they reached 5 years of age.

Epidemics of poliomyelitis first began to appear in Europe and the United States during the latter part of the 19th century; they continued with increasing frequency in economically advanced countries until the introduction of effective vaccines in the 1950s and 1960s.^{104,238,503,894} The evolution from endemic to epidemic follows a characteristic pattern beginning with collections of a few cases, then endemic rates that are higher than usual, followed by severe epidemics with high attack rates. The age group attacked in endemic areas and in early epidemics is the youngest; more than 90% of paralytic cases begin in children younger than 5 years of age. Once this pattern of epidemicity begins, it is irreversible unless preventive vaccination is performed.

As epidemics recur over a period of years, a shift in age incidence occurs whereby relatively fewer cases are seen in the youngest children; the peak often is in the 5- to 14-year-old group, and increasing percentages of cases develop in young adults. These changes are correlated with socioeconomic factors and improved standards of hygiene—when children are protected from immunizing infections in the first few years of life, the pool of susceptible persons builds up, and introduction of a virulent strain often is followed by an epidemic.⁵⁰³ The extensive use of vaccines since the late 1950s resulted in the elimination of paralytic poliomyelitis from large geographic areas, but the disease remains endemic in various parts of the world. Although seasonal periodicity is distinct in temperate climates, some viral activity does take place during the winter months.²⁰⁰ Infection and the acquisition of postinfection immunity occur with greater intensity and at earlier ages in crowded, economically deprived populations with less efficient sanitation.

Molecular techniques have allowed researchers to study the genotypes of specific viral types in populations over the course of time.^{308,545,706,814} For example, Mulders and colleagues⁸¹⁴ studied the molecular epidemiology of wild poliovirus 1 in Europe, the Middle East, and the Indian subcontinent. These investigators found that four major genotypes were circulating. Two genotypes were found predominantly in Eastern Europe, a third genotype was circulating mainly in Egypt, and the fourth genotype was dispersed widely. All four genotypes were present in Pakistan.

Prevalence of Different Types

The epidemiologic behavior of coxsackieviruses and echoviruses parallels that of polioviruses, in which unrecognized infections far outnumber

infections with distinctive symptoms. The agents are disseminated widely throughout the world, and outbreaks caused by one or another type occur regularly. These outbreaks tend to be localized, with different agents prevalent in different years. In the late 1950s, however, echovirus 9 had a far wider circulation; it swept through a large part of the world and infected not only children but also young adults.

Coxsackievirus A16 viral infection with hand-foot-and-mouth disease first was noted in Toronto and New Zealand in 1957.²¹¹ Subsequently, illness caused by this virus was noted throughout the world. Antibody studies and viral isolation studies in 1957 to 1963 in California and Wisconsin indicated that coxsackievirus A16 was a newly circulating virus.^{205,211} Since the 1960s, coxsackievirus A16 outbreaks of hand-foot-and-mouth disease continued to occur in the United States. However, since 1968, this virus has not been one of the five most prevalent yearly isolates (Table 166.4).

EV 71 was first isolated in California from patients with aseptic meningitis from 1969 to 1972.^{872,1003} Subsequently, this virus has been noted in the United States in association with aseptic meningitis and occasionally with encephalitis. The clinical manifestations of EV 71 changed, and the chronology of this change is presented by Ooi and colleagues.⁸⁷² In addition to aseptic meningitis, hand-foot-and-mouth disease and a broad range of encephalitis presentations (e.g., paralytic disease and brainstem encephalitis) occurred. In Japan, in 1973, 1977, and 1978, 1031 cases occurred; most patients had hand-foot-and-mouth disease. Since 1997, severe hand-foot-and-mouth disease with paralysis, cardiorespiratory dysfunction, and brainstem encephalitis has had epidemic occurrence in Malaysia, Taiwan, Singapore, Brunei, Japan, China, and other Asian-Pacific countries.^{225,226,432,1081}

Although severe EV 71 disease has occurred occasionally in North America and Western Europe, epidemics similar to those occurring in the Asian-Pacific region have not been noted.^{53,786,872} The three genotypes of EV 71 are A, B, and C. B and C have subtypes B 1 to 5 and C 1 to 5. However, a clear association does not appear to exist with specific subtypes and the occurrence of more severe disease. Chang and colleagues¹⁷⁹ found that the human leukocyte antigen (HLA)-A33 phenotype was associated with EV 71 infections. This HLA-A33 phenotype is common in Asian populations but is rare in white populations. This finding suggests a possible reason for the difference in epidemic occurrence in the Asian-Pacific region and the United States and Western Europe.

After a long absence, a particular agent may return and circulate among susceptible persons of different ages who have been born since the last epidemic. Other agents remain endemic in a given area and surface as sporadic cases and occasionally in small outbreaks. Multiple types frequently are active at the same time, although one agent commonly is predominant in a given locality.

Listed in Table 166.4 are the five most prevalent nonpolio enteroviral isolations per year in the United States from 1961 through 2013.^{3,155,162,164,168,189,190,200,1057}

Most patients from whom viruses were isolated had neurologic illnesses. Other EVs also possibly were prevalent but did not cause clinical disease sufficiently severe enough to induce physicians to submit specimens for study. In addition, probably many coxsackievirus A infections, even in epidemic situations, have gone undiagnosed because inoculation of suckling mice was not performed. Although more than 62 nonpolio EV types and 16 PeV types have been identified, of interest is that in the 53 years covered in Table 166.4, only 26 different virus types are noted. Khetsuriani and associates¹⁶⁶ at the CDC presented an extensive report on enteroviral surveillance in the United States for the period from 1970 to 2005. During this period, the most common enteroviral isolates, in order, were as follows: echoviruses 9, 11, and 30; coxsackievirus B5; and echovirus 6. During the period from 2000 to 2005, the most common isolates, in order, were echoviruses 9, 30, 18, and 13 and coxsackievirus B5. The extensive EV surveillance report (between 1970 and 2005) contained data on both serotype and genomic species designation.¹⁶⁶ Of 49,637 viral isolates, 58 different EV serotypes and 2 PeV serotypes were identified. Of these isolates, 94.6%, 3.1%, 0.3%, and 0.1% were genomic species EV-B, EV-A, EV-C, and EV-D, respectively, and 1.9% were PeVs. Similar serotype and genomic species data are also available for 2006 to 2008.¹⁶⁸ During this

period, 15 serotypes were identified, 13 of which were genomic species EV-B.

Similar data for the most common enteroviral isolates in Spain from 1988 to 1997 and in Belgium from 1980 to 1994 are available.^{314,1099} The EV isolated most frequently in both countries was echovirus 30. In 1997 and 1998, major epidemic disease caused by EV 71 occurred in Taiwan, Malaysia, Australia, and Japan.^{122,176,491,646,759}

Even though the use of live polioviral vaccine has eliminated epidemic poliomyelitis in the United States, determining the effect of polio vaccine viruses on EV ecology has been difficult. In 1970, polioviruses accounted for only 6% of the total number of enteroviral isolations from patients with neurologic illnesses.²⁰⁰ Although the numbers are not directly comparable, more than one-third of the enteroviral isolations in 1962 from similar patients were polioviruses.²⁰⁰ However, Horstmann and colleagues⁵⁰⁴ studied specimens from sewage and from asymptomatic children during the early vaccine era and noted that the number of yearly polioviral isolations (presumably vaccine strains) was greater than the number of nonpolio EVs. The prevalence of vaccine viruses apparently did not affect the seasonal epidemiology of other EVs.

PATHOGENESIS AND PATHOLOGY

Events During Pathogenesis

Fig. 166.4 diagrams the events in pathogenesis. After initial acquisition of virus by the oral or respiratory route, implantation occurs in the pharynx and the lower alimentary tract.^{104,200,200,771,880,979} Within 1 day, the infection extends to the regional lymph nodes. On approximately the third day, minor viremia develops and results in the involvement of many secondary infection sites. In congenital infections, the infection is initiated during the minor viremia phase. Multiplication of virus in secondary infection sites coincides with the onset of clinical symptoms. Illness can vary from minor infection to fatal disease. Major viremia occurs during the period of multiplication of virus in secondary infection sites; this period usually lasts from the third to the seventh day of infection. In many echovirus and coxsackievirus infections, involvement of the CNS apparently occurs at the same time as other secondary organ involvement. Occasionally, the CNS symptoms of enteroviral infections are delayed, thus suggesting that seeding occurred later in association with the major viremic phase.

Cessation of viremia correlates with the appearance of serum antibody. The viral concentration in secondary infection sites begins to diminish on approximately the seventh day. However, infection continues in the lower intestinal tract for prolonged periods.

In Fig. 166.5, clinical and subclinical events in polioviral infections are presented. By 3 to 5 days after exposure, virus can be recovered from blood, the throat, and feces. This finding may be accompanied by symptoms of the “minor illness,” or the infection may be unrecognized clinically. The end of the period of viremia coincides with the appearance of antibodies and the onset of clinical signs of CNS involvement. The available evidence favors blood as the main pathway of CNS invasion in natural disease, but experimental infections in monkeys indicated that the virus can travel along the axons of peripheral nerves. Possibly, when tonsillectomy is performed on a child with an inapparent poliovirus infection, the virus enters the nerve fibers exposed during surgery and spreads to the cranial nerve nuclei in the brain, thereby resulting in bulbar paralysis.

Factors That Affect Pathogenesis

The pathogenesis and pathology of EVs, PeVs, and SAFVs infections depend on the virulence, tropism, and inoculum concentration of virus, as well as on many specific host factors. EVs, PeVs, and SAFVs obviously have marked differences in both tropism and virulence. Although some generalizations can be made with regard to tropism, marked differences occur even among strains of specific viral types. Differences in the virulence of specific viral types may be the result of recombination or point mutations.^{933,951,992}

Van Eden and associates¹¹¹⁷ studied 17 families during an outbreak of poliomyelitis caused by type 1 virus in the Netherlands. The findings suggested that HLA-related genetic factors were important in the

occurrence of paralytic disease. In a study of 219 EV 71 cases and 97 control children in Taiwan, Chang and associates¹⁷⁸ found that susceptibility was related to HLA-A33. The phenotypic frequency of HLA-A33 is approximately 17% to 35% in Asian populations, whereas it is only 0% to 1% in white populations. These investigators suggest that this population genetic difference may explain the general lack of severe EV 71 disease (with encephalitis or polio-like syndrome with or without cardiopulmonary failure) in the United States. The greatest risk factor in this study, however, was male sex.

EV and PeV infections in the fetus and neonate generally are thought to be more severe than similar infections in older persons. This situation undoubtedly is the case with coxsackievirus B infection and probably also with coxsackievirus A, echovirus and PeV infections. Although the reasons for this increased severity are unknown, several aspects of neonatal immune mechanisms have been suggested. In addition, the similarity of coxsackievirus B infections in suckling mice to those in human neonates provided a useful animal model system. Heineberg and associates⁴⁷² compared coxsackievirus B1 infections in 24-hour-old suckling mice with similar infections in older mice. These investigators noted that adult mice produced interferon in all infected tissues, whereas suckling mice produced only small amounts of interferon in the liver. These researchers thought that the difference in outcome of coxsackievirus B1 infection in suckling and older mice could be explained by the inability of cells of the immature animals to elaborate interferon. Additional studies of abnormalities of innate immunity in neonates may enhance our understanding of the severity of enteroviral infections in newborns.⁶⁹²

Other researchers suggested that the increased susceptibility of suckling mice to severe coxsackievirus infections is related to the transplacentally acquired, increased concentrations of adrenocortical hormones.^{73,106} Kunin⁶⁵⁸ suggested that the difference in age-specific susceptibility could be explained at the cellular level. He showed that various tissues of newborn mice bind coxsackievirus B3, whereas tissues of adult mice are virtually inactive in this regard.^{658,657} The

FIG. 166.5 Course of clinical and subclinical forms of poliovirus infection in relation to the presence of virus and the development of antibodies. CNS, Central nervous system; Comp., Complement. progressive loss of receptor-containing cells with increasing age may be the mechanism that accounts for less severe infections in older animals. Supporting this suggestion, Ito and colleagues⁵³⁰ showed that expression of coxsackievirus and adenovirus receptor (CAR) decreases with increasing age in rats. In the past, researchers assumed that specific disease in various organs and tissues in enteroviral infections was caused by the direct cytopathic effect and tropism of a particular virus. In more recent years, however, large numbers of studies using murine model systems suggested that host immune responses contribute to the pathologic process.^{*,x} These studies suggested that T-cell-mediated processes and virus-induced autoimmunity cause both acute and chronic tissue damage. In contrast, other studies suggested that the primary viral cytopathic effect is responsible for the tissue damage and that the various T-cell responses are a reaction to the damage and not its cause.⁷⁵⁷

Since the early 1960s, the clinical manifestations caused by several enteroviral serotypes have changed. For example, echovirus 11 infection initially was noted in association with an outbreak of upper respiratory tract infection in a day care center in 1958.⁹⁰⁴ Then, in the 1960s, this infection was found to be related to exanthem and aseptic meningitis.^{204,210} Following this event and occurring in the 1980s was the association of echovirus 11 infection and severe sepsis-like illness with hepatitis in neonates.^{107,200,200,449,579,789,809}

Another example relates to EV 71 infections. Initially, this virus was noted in association with aseptic meningitis, and only a few patients also had exanthem.^{609,1003} Since the late 1990s, severe epidemic disease with EV 71 has occurred in Taiwan, Singapore, Australia, Malaysia, and Japan. In these epidemics, hand-foot-and-mouth disease is a major finding, and the neurologic disease is more severe than in the past.[†]

These phenotypic changes could be the result either of point mutations or of recombination among EVs.^{173,215,613,719,720,863,992,1030} Chan and AbuBaker¹⁷³ presented evidence indicating that a recombination event occurred between EV 71 and coxsackievirus A16.

PATHOLOGY

The clinical signs of enteroviral infection vary widely, so great variations in pathology also exist. Because pathologic material generally is available only from patients with fatal illness, this section discusses only the more severe manifestations. Worth emphasizing, however, is that these fatal infections account for just a small portion of all enteroviral infections. The pathologic findings in children with milder infections, such as nonspecific febrile illness, have not been described.

Coxsackieviruses A

Records of severe illness associated with coxsackieviruses A are rare. Gold and colleagues,⁴¹⁶ in a study of sudden unexpected death in infants, recovered coxsackievirus A4 from the brains of three children. In none of these patients were histologic abnormalities noted in the brain or spinal cord. An adult with a fatal coxsackievirus A7 infection had diffuse pancarditis and organized pneumonitis.⁵⁵

Coxsackieviruses B

Of the nonpolio EVs, group B coxsackieviruses have been associated most frequently with severe and catastrophic disease. The most common findings in these cases have been myocarditis, meningoencephalitis, or both. Involvement of the adrenals, pancreas, liver, and lungs also has been noted.

Heart

Grossly, the heart usually is enlarged, with dilation of the chambers and flabby musculature.^{197,346,398,1180} Microscopically, the pericardium frequently contains some inflammatory cells along with thickening and

FIG. 166.6 Coxsackievirus B4 myocarditis in a 9-day-old infant. Note the myocardial necrosis and mononuclear cellular infiltration. (From Cherry JD. Enteroviruses. In: Remington JS, Klein JO, eds. *Infectious Diseases of the Fetus and Newborn Infant*. Philadelphia, PA: WB Saunders; 1976.)

edema, and the endocardium may have focal infiltrations of inflammatory cells. The myocardium (Fig. 166.6) is congested and contains infiltrations of inflammatory cells (i.e., lymphocytes, mononuclear cells, reticulum cells, histiocytes, plasma cells, and polymorphonuclear and eosinophil leukocytes). Involvement of the myocardium often is patchy and focal but occasionally diffuse. The muscle shows loss of striation, as well as edema and eosinophilic degeneration. Muscle necrosis without extensive cellular infiltration is a common finding.

Brain and Spinal Cord

The meninges are congested, edematous, and occasionally mildly infiltrated with inflammatory cells.^{200,346,798,1180} Lesions in the brain and spinal cord are focal rather than diffuse, but they frequently involve many different areas. The lesions consist of areas of eosinophilic degeneration of cortical cells, clusters of mononuclear and glial cells (Fig. 166.7), and perivascular cuffing. Two children with fatal coxsackieviral B infection (types 2 and 4) had, in addition to typical inflammatory encephalitic lesions, widespread multifocal areas of liquefaction necrosis without inflammation.³³⁷

Other Organs

The lungs frequently have areas of mild focal pneumonitis with peribronchiolar mononuclear cellular infiltration.^{15,123,200,396,798} The liver often is engorged and occasionally contains isolated foci of liver cell necrosis and mononuclear infiltration. In the pancreas, occasional focal degeneration of islet cells occurs. Congestion has been observed in the adrenal glands, along with mild to severe cortical necrosis; inflammatory cells are present.

Echoviruses

Although frequently responsible for illness, echoviruses rarely were associated with fatal infection until relatively recently. In several different reports with eight different echovirus types, hepatic necrosis was a major pathologic finding.^{97,200,401,449,789,809,1186} Massive hepatic necrosis has been seen with echoviruses 3, 6, 7, 9, 11, 14, 19, and 21. At autopsy, one infant with echovirus 6 infection had cloudy and thickened leptomeninges, liver necrosis, adrenal and renal hemorrhage, and mild interstitial pneumonitis.²⁰⁰ One infant with echovirus 9 infection had an enlarged and congested liver with marked central necrosis,²⁰⁰ and another with

this virus had interstitial pneumonitis without liver involvement.²⁰⁰ Three infants with echovirus 11 infection had renal and adrenal hemorrhage and small vessel thrombi in the renal medulla and in both the medulla and inner cortex of the adrenal glands.⁸¹⁸ These patients' livers were normal. Two infants, one with echovirus 6 and the other with echovirus 31 infection, had only extensive pneumonia.^{114,200}

Enteroviruses

Enterovirus D68

Kreuter and associates⁶⁵¹ described the pathologic findings in a fatal CNS EV D68 infection in a 5-year-old boy. The lungs were three times the normal weight for age. On microscopic evaluation, mixed pneumonia with hemorrhage was noted. The spleen was twice the normal weight for age; microscopically, follicular hyperplasia was present. The brain had profound edema. On microscopic study, the neurons in the hippocampus were hyper eosinophilic with pyknotic nuclei. The meninges, cerebellum, midbrain, pons, medulla, and cervical spinal cord all had lymphocytic meningomyelitis and encephalitis. The motor nuclei demonstrated neurophagia.

Enterovirus 71

Teoh and colleagues¹⁰⁸¹ described the clinical characteristics and functional motor outcomes of EV 71 neurologic disease in 61 children. Four precipitous deaths occurred in this group. The pathologic findings of the brain and brainstem in two of the fatal cases were described. Severe inflammation that mainly involved the medulla was noted. Examiners observed numerous perivascular and interstitial activated microglia, macrophages, and lymphocytes. Findings also included scattered microglial nodules and areas of necrosis; rare foci of neurophagia were seen.

The brain of a child who died of acute encephalitis caused by EV 71 infection was examined.¹¹⁹³ Grossly, the brain appeared normal, but microscopically, it revealed typical features of acute encephalitis consisting of perivascular cuffing with mixed inflammatory cells, neuronophagia, and inflammatory nodules.

Parechoviruses

Although parechoviral infections have a broad spectrum of clinical manifestations, including encephalitis and sepsis-like neonatal disease,

it is surprising that deaths have not been reported, and therefore pathologic data are not available.*

Saffold Virus

SAFV was detected in the myocardium, lung tissue, and blood of a 2-year, 7-month-old previously healthy boy who died unexpectedly after 1 day of low-grade fever.⁸³⁹ The heart microscopic examination revealed acute lymphocytic myocarditis.

Polioviruses

The neuropathy of poliomyelitis usually is pathognomonic; only certain cells and areas of the neuraxis are susceptible to the virus.^{104,238} Neuronal damage is caused directly by virus multiplication, but not all affected neurons are killed. The injury may be reversible, and function may be restored within 3 to 4 weeks after onset. Little histologic evidence of meningeal reaction exists. Perivascular cuffing and some interstitial glial infiltration are present. Histologic sections generally reveal more widespread lesions than would be estimated from the clinical findings. Scattered neurons may undergo considerable destruction without causing clinical disability.

Regions in which neuronal lesions occur are (1) the spinal cord (anterior horn cells chiefly and, to a lesser degree, the intermediate and dorsal horn and dorsal root ganglia), (2) the medulla (vestibular nuclei, cranial nerve nuclei, and the reticular formation that contains the vital centers), (3) the cerebellum (nuclei in the roof and vermis only), (4) the midbrain (chiefly the gray matter but also the substantia nigra and occasionally the red nucleus), (5) the thalamus and hypothalamus, (6) the pallidum, and (7) the cerebral cortex (motor cortex). The viruses spare the following areas: (1) the entire cerebral cortex, except the motor area; (2) the cerebellum, except the vermis and deep midline nuclei; and (3) the white matter of the spinal cord. This distribution of lesions permits the physician to establish a histologic diagnosis of poliomyelitis.

Extraneural disease usually is a secondary phenomenon. Bronchopulmonary changes such as aspiration pneumonia, atelectasis, and purulent bronchitis may be caused by impaired coughing and decreased thoracic movement. Cardiovascular changes may result in hypertension, cardiac failure, and pulmonary edema. Prolonged immobilization leads to negative nitrogen and calcium balance, along with urinary lithiasis, renal failure, hypertension with encephalopathy, and seizures. Treatment itself may cause untoward complications, such as urinary tract infection (after catheterization), decubitus ulcers, and psychotic disturbances. Ulcerations in the alimentary tract may result in serious bleeding and occasional perforation. Respiratory failure culminates in respiratory acidosis and anoxic changes.

CLINICAL MANIFESTATIONS: NONPOLIO ENTEROVIRUSES, PARECHOVIRUSES, AND SAFFOLD VIRUSES

Nonpolio enteroviral, parechoviral, and Saffold viral infections are exceedingly common, and the spectrum of disease is protean. Many of the clinical-virologic associations listed in [Tables 166.5 through 166.19](#) are made on the basis of a limited number of cases. Because EVs, PeVs, and SAFVs frequently are carried asymptomatically in the gastrointestinal tract for relatively long periods, some of the observed illnesses and the viruses concomitantly recovered may not have a cause-and-effect relationship. However, repeated observations since the 1960s have supported many virus-illness associations, even though their occurrence has been sporadic.

Few specific EV, PeV, or SAFV diseases exist, but, rather, various interrelated syndromes and anatomically associated illnesses are reported. Many illnesses and syndromes can be caused by different viral types, and most types are capable of inducing a variety of clinical syndromes. Conversely, certain specific coxsackieviral, echoviral, and enteroviral types have clinical characteristics that facilitate an etiologic diagnosis.

*References 4, 89, 109, 119, 284, 552, 596, 619, 645, 680, 859, 885, 1022, 1038, 1151.

Since the late 1980s, few careful studies (with the exception of clinical experiences with EVs D68 and 71 and PeV 3.) have been conducted in which specific clinical findings were correlated with individual enteroviral types. This paucity of studies was fostered by the expense of serotyping and the lack of using inoculation of suckling mice for isolation of virus. The increased use of polymerase chain reaction (PCR) also has contributed to the lack of identification of manifestations of disease by specific viral type. This situation is unfortunate because the clinical manifestations caused by specific viral types are not constant, and disease severity varies by specific enteroviral type.

Asymptomatic Infection

Because researchers have known that 90% to 95% of poliovirus infections are not recognized clinically, they have assumed that most infections with EVs, PeVs, and SAFVs are asymptomatic. This opinion is strengthened by the finding that these viruses can be recovered frequently from the stools of healthy children. However, relatively few data are available on the rate of asymptomatic infection with nonpolio EVs, PeVs, and SAFVs. All too frequently, isolation of EVs and PeVs from stool is equated with asymptomatic infection. This assumption is an error because illness, if it takes place, occurs shortly after the acquisition of virus and is short-lived; a particular infection may have been associated with a nonspecific illness 2 or 3 months before a stool specimen is obtained in a surveillance program. Unfortunately, in several studies involving controlled population groups in which accurate clinical expression rates could have been determined, clinical observations apparently were of secondary importance to the investigators.^{200,399,400,402,644} The data available suggest differences in clinical expression among coxsackieviral and echoviral types.

Table 166.5 lists the approximate frequency of asymptomatic infections with selected coxsackieviruses and echoviruses. As can be seen, the rates vary among the group as a whole and even within specific types. Overall, approximately one-half, and perhaps more, of all nonpolio enteroviral infections appear to be associated with clinical manifestations. In general, the more carefully clinical symptoms are examined, the smaller is the percentage of truly asymptomatic infections. Clinical expression also is related inversely to age. With coxsackievirus A16, asymptomatic infection occurs in only approximately 10% of children younger than 5 years of age, whereas rates are higher in older children and adults.^{13,200} Sabin⁹⁷⁸ reported no asymptomatic infections in infants with echovirus 18, and Nishimi and Yodfat⁸⁴⁵ noted fewer than 20% of infections without illness in children younger than 8 years of age during an echovirus 4 epidemic. At the other extreme, Clemmer and associates²⁴⁸

reported that 96% of infections with coxsackievirus B3 were asymptomatic. In other studies, the illness rate of coxsackievirus B3 was 60% to 75%. Extensive seroepidemiologic studies by Zoll and colleagues¹²¹⁸ and Galama and associates³⁸¹ of SAFV types 2 and 3 indicate that infection is very common in young children with these viruses. Because other studies have only occasionally noted clinical associations with these viruses, it appears that Saffold viral infections are most often asymptomatic.*

Since 2008, EV D68 has caused severe respiratory and neurologic illnesses but the rate of asymptomatic infection with this virus is unknown.[†]

Similarly, EV 71 has caused hand-foot-and-mouth syndrome and severe neurologic illness, but the rate of asymptomatic infections with this virus also is unknown.[‡]

Asymptomatic infections in neonates with PeV 1 were noted on three occasions in the late 1960s and 1970.^{93,824}

Nonspecific Febrile Illness

Nonspecific febrile illness is the most common manifestation of coxsackieviral and echoviral infection (Table 166.6). All viral types cause this clinical finding, but its frequency varies considerably among the individual viruses.

The onset of illness usually is abrupt, without a prodrome. In young children, the initial finding is fever and associated malaise. In older children, headache generally is noted. The temperature ranges between 38.3°C and 40° (101°F and 104°F) and has a mean duration of 3 days. In some instances, the fever is biphasic; it occurs for 1 day, is absent for 2 to 3 days, and then recurs for an additional 2 to 4 days. In many young children, the only manifestation of illness is fever, and its presence is discovered by chance by a parent.

Malaise and anorexia often are related to the degree of temperature elevation, as is headache in older patients. Sore throat is a common complaint, but an inflamed pharynx is not seen on examination. Nausea and vomiting occasionally occur at the onset of illness, as does mild abdominal discomfort. One or two loose stools may be noted. Generalized myalgia also is observed, and children complain of a scratchy feeling in the throat.

Physical examination usually yields benign findings. Minimal conjunctivitis, infection of the pharynx, and cervical lymphadenitis may be present. The duration of illness varies from 24 hours to approximately 6 days, with an average of 3 to 4 days. The white blood cell count (WBC) count is normal. EVs, particularly coxsackieviruses A, are significant causes of febrile seizures in young children.⁵⁰⁹ An SAFV was noted in a stool sample from a child with a fever of unknown origin.⁵⁸⁰

Respiratory Manifestations

Common Cold

Although numerous coxsackieviruses and echoviruses have been recovered from children with mild upper respiratory tract infections, only rarely do the illnesses qualify as common colds (see Chapter 7; Table 166.6). (The common cold is an acute illness with nasal stuffiness, rhinitis, no objective evidence of pharyngitis, and no or minimal fever.) In most instances, significant fever (temperature >38.3°C [>101°F]) is associated with enteroviral infections and usually some degree of pharyngitis.

Coxsackievirus A21 is the only EV that clearly qualifies as a common cold virus.^{200,569} This agent has produced epidemics of mild respiratory illness in military populations. In adult volunteers, instillation of this virus in the nose has resulted in the common cold syndrome. Epidemic disease has not been observed in children. Other viruses that have been associated with the common cold syndrome include echoviruses 2 and 20 and coxsackieviruses B1 to B6 and A24.²⁰⁰

TABLE 166.5 Approximate Frequencies of Asymptomatic Infection With Selected Coxsackieviruses and Echoviruses

Virus	Asymptomatic Infection Frequency (%)
Coxsackieviruses	
A	50

Pharyngitis (Pharyngitis, Tonsillitis, Tonsillopharyngitis, and Nasopharyngitis)

Pharyngitis is a common clinical manifestation of coxsackieviral and echoviral infection (see Chapter 9). Probably all EVs on occasion cause mild pharyngitis. The most common coxsackieviruses and echoviruses associated with pharyngitis are as follows: coxsackieviruses A9, B1, B2, B3, B4, and B5; echoviruses 2, 4, 6, 9, 11, 16, 19, 25, and 30; and EV 71.*

Pharyngitis in coxsackievirus and echovirus infections frequently is associated with other clinical findings, such as meningitis, pleurodynia, and exanthem. These other manifestations become more important than pharyngitis in individual cases in the minds of parents as well as clinicians.

Pharyngitis caused by coxsackieviruses and echoviruses usually is abrupt in onset, without a prodrome. Although pharyngeal involvement is present at the onset of disease, the initial complaint usually is fever. The temperature usually ranges between 38.3°C and 40°C (101°F and 104°F), but higher temperatures are not unusual. In general, fever tends to be more pronounced in younger patients. Young children have malaise and anorexia. School-age children complain of headache and myalgia. Sore throat, coryza, and vomiting, diarrhea, or a combination thereof also may be noted.

Examination of the tonsils and pharynx shows varying degrees of erythema. In some cases, only infection is noted, whereas in others, severe pharyngitis with patches of exudate is seen. The usual duration of uncomplicated coxsackieviral or echoviral pharyngitis is 3 to 6 days. Routine laboratory study is of minimal value in enteroviral pharyngitis; the total WBC count may be normal or slightly elevated with a normal differential determination. Throat culture rules out disease caused by group A streptococci.

SAFV 2 was noted in 13 children with pharyngitis and 12 children with tonsillitis in a Japanese study.⁵⁴⁷ Also in Japan, two children with SAFV 3 were noted to have tonsillitis.¹¹⁰⁵

Other Intraoral Manifestations

Herpangina. The onset of herpangina is typical of most EV infections and is characterized by the sudden awareness of fever.^{889,1144,1210,1209} No characteristic prodrome usually exists, but young children may be irritable and occasionally listless and anorexic for a few hours before the febrile state is recognized. The initial temperature can be variable, with a range from normal to 41°C (106°F). In general, the temperature tends to be higher in younger patients. Breese¹¹⁷ noted that the most common temperature in young children was between 39.5°C and 40°C (103°F and 104°F). Older children frequently complain of headache and backache. Vomiting occurs in approximately 25% of children younger than 5 years of age. In one outbreak of illness caused by coxsackievirus A4,³⁶⁰ initial symptoms were as follows: anorexia and drooling (100%); sore throat (50%); coryza (45%); headache (18%); and vomiting, diarrhea, or both (36%).

In most instances of herpangina, the oropharyngeal lesions are present on the first examination at the time of fever or shortly after fever is noted. In the coxsackievirus A4 outbreak described by Forman and Cherry,³⁶⁰ the enanthem was not observed until 24 to 48 hours after the onset of initial nonspecific symptoms. The characteristic lesions in herpangina are small (1–2 mm) vesicles and ulcers. These lesions apparently start as papules, become vesicular, and then ulcerate in a short but variable period. In the experience of one of us (J.D.C.), the lesions most commonly observed are ulcers. Breese¹¹⁷ noted in some children seen early in the course of the illness that a petechial appearance preceded the appearance of typical vesicular-ulcerative enanthem.

The lesions usually are discrete, with an average of 5 per patient; some patients have only 1 or 2 lesions, whereas others may have 14 or more. When seen early, the vesicular lesions are observed to enlarge from 1 to 2 mm to 3 to 4 mm during a 2- to 3-day period.⁸⁸⁹ Each vesicular and ulcerative lesion is surrounded by an erythematous ring that varies in size up to 10 mm in diameter. The most common sites of the lesions are the anterior tonsillar pillars. Lesions also occur on the soft palate, uvula, tonsils, and pharyngeal wall and occasionally on the posterior buccal surfaces. In some cases, additional lesions have

*References 200, 208–210, 262, 339, 450, 468, 597, 598, 608, 623, 685–687, 807, 976, 981, 1028.

been noted on the dorsum or tip of the tongue. However, by definition, cases in which the primary involvement is on the tongue or anterior mouth and in which the lesions are of a general size greater than 5 mm are not considered to be herpangina.

Aside from the specific lesions, the remainder of the throat appears normal, minimally injected, or mildly erythematous. The usual duration of signs and symptoms is 3 to 6 days. Most cases of herpangina are mild and without complications, but aseptic meningitis and other more severe enteroviral manifestations also occur occasionally. Severe neurologic manifestations have been observed in children with herpangina caused by EV 71.^{179,182,491,646} During epidemic disease in Taiwan in 1998, children with herpangina and aseptic meningitis, acute flaccid paralysis, and rhombencephalitis were described.^{491,518} In one study, a biphasic course was described, with herpangina occurring first and neurologic manifestations 2 to 5 days later.⁴⁸⁸

EVs, PeVs, and SAFVs found in association with sporadic or epidemic herpangina occurrence are presented in Table 166.7.

Acute lymphonodular pharyngitis. In 1962, Steigman and colleagues¹⁰⁴⁹ reported a unique enanthem associated with coxsackievirus A10 infection. The lesions had the typical distribution of herpangina; they were papular, discrete, 3 mm in diameter, and surrounded by a zone of erythema. The lesions were white to yellow and persisted for 6 to 10 days. This entity has not been reported again, although coxsackievirus A10 has been noted in association with hand-foot-and-mouth disease.^{200,1012}

Stomatitis and other lesions in the anterior of the mouth. Historically, the main enteroviral cause of stomatitis and ulcerative lesions in the anterior of the mouth was coxsackievirus A16, and the clinical entity was hand-foot-and-mouth disease. This condition is presented in detail

later in this chapter. Worth mentioning here, however, is that occasionally enanthem occurs without the exanthem, and this enanthem also has been associated with other coxsackieviruses (A5, A9, A10, B2, B5), echovirus 33, and in more recent years EV 71.^{200,225,226,286,315,356,432,707,1012,1081}

In echovirus 9 infection, Tyrrell and colleagues¹¹¹⁰ reported six children with a unique enanthem: painless whitish dots, ulcers, or vesicles on the buccal surfaces near the Stensen duct. These investigators also noted the occasional occurrence of similar lesions under the tongue.

Deseda-Tous and colleagues²⁹⁴ reported an adolescent with hemorrhagic vesicular lesions on the pharynx, mucosal surfaces, and tongue in association with an echovirus 11 infection. Clarke and Stott²⁴⁵ observed reddish macules on the buccal mucosa of a patient with echovirus 20 infection, and Cherry and Jahn²⁰³ noted a child with hand-foot-and-mouth disease in whom the buccal lesions suggested Koplik spots, although the lesions were larger and yellower in this patient.

Parotitis

Parotitis in association with herpangina and coxsackievirus A infection was reported in 1957 by Howlett and associates.⁵¹² In 1960, Kraus⁶⁵⁰ described two additional cases, and Bertaggia and associates⁹⁸ and Winsser and Altieri¹¹⁷⁶ noted parotitis in association with coxsackieviruses B3 and B4, respectively. Three patients with acute hemorrhagic conjunctivitis and parotitis caused by EV 70 also have been reported.⁹⁹⁷

Croup

In large studies of respiratory illness in young children, croup is associated sporadically with coxsackieviral and echoviral infection.^{187,200,366,407,1161} In general, these illnesses are mild, in contrast to croup caused by parainfluenza and influenza viruses.

An outbreak of croup associated with echovirus 11 in a day care center was reported.⁹⁰⁴ In this instance, 17 of 53 ill children were found to be infected with the U strain of echovirus 11. A subsequent study noted the same virus in 4 children with croup.⁹⁰⁵ Croup also was reported in outbreaks of coxsackievirus B5 infection.^{51,260} Other specific agents associated with croup include coxsackieviruses A9 and B4 and echoviruses 4 and 21.²⁰⁰

Bronchitis (Not Including Enterovirus D68)

An acute febrile illness with cough, rhonchi, and referred breath sounds occasionally is a sporadic manifestation of enteroviral infection. A specific association of coxsackieviruses B1 and B4, echoviruses 8, 12, 13, and 14, and PeV 1 has been found.^{187,200,260,322,324} SAFV type 2 was noted in one child with bronchitis.⁵⁴⁷

Bronchiolitis and Infectious Asthma (Not Including Enterovirus D68)

Coxsackieviruses and echoviruses have been associated sporadically with bronchiolitis, infectious asthma, and the precipitation of asthmatic attacks in atopic children.^{187,200,322,366,407,429,499,1161} Epidemic disease has not been observed, and the illnesses usually have been mild.

Pneumonia (Not Including Enterovirus D68)

In general, studies of respiratory tract infections in children, sporadic coxsackieviruses, and echoviruses have been noted in 1% to 7% of patients with pneumonia and positive viral cultures.^{187,200,366,407} Specific virus types include the following: coxsackieviruses A9, A16, B1, B2, B3, B4, B5, and B6; echoviruses 6, 7, 9, 11, 12, 19, 20, and 30; EV 71; and SAFV (type not identified).*

In only three instances can an outbreak of pneumonia caused by specific viruses be suggested to have occurred. During the summer of 1959, Lerner and colleagues⁶⁸⁸ noted that 3 of 15 children infected with coxsackievirus A9 had pneumonia. The patients with pneumonia had a vesicular rash, and one of these children died.

Eckert and associates³²² observed six children with coxsackievirus B1 infection and pneumonia during the summer of 1963. These illnesses were not described further, although the mean WBC count in 12 children who had lower respiratory tract infections with group B coxsackieviruses

was reported as 11,383 with a normal differential. All children were hospitalized.

Goldwater⁴¹⁸ reported a coxsackievirus B6 outbreak in south Australia during the summer of 1992 to 1993. Twenty-seven patients had pneumonia associated with high fever and severe cough that lasted several weeks. In addition to the fatal case of coxsackievirus A9 infection described by Lerner and colleagues,⁶⁸⁸ deaths have resulted from infection with coxsackieviruses B1, B5, and A16.^{355,558,1188}

In the Philippines in 2009, 21 children with EV 68, severe respiratory tract infections, and presumed pneumonia were noted.⁵³⁷ All children had cough and chest indrawing. Two deaths occurred.

Enterovirus D68 (Bronchitis, Bronchiolitis, and Pneumonia)

In California between October and December 1962, EV D68 was isolated from throat swabs of four children with acute lower respiratory tract illness.⁹⁹⁸ All these children had pneumonia and “wheezing characteristic of bronchiolitis.” This virus was not noticed in association with respiratory illnesses for about 40 years after 1962.¹⁰⁰⁷ Between 2005 and 2011, small outbreaks of respiratory disease with EV D68 were observed in Asia, Europe, and the United States.^{146,495,537–539,587,717,864,1007} In 2014, EV D68 respiratory illness was widespread throughout the United States and Canada.^{266,495,778,781,876,1037} In 2013 and 2014, widespread respiratory illness with EV D68 was noted in Europe and South America.^{108,138,1007,1093}

Holm-Hansen⁴⁹⁵ reviewed the clinical characteristics of 195 children noted in 19 published papers. She noted the following: cough, 75%; fever, 44%; wheeze, 40%; chest indrawing, 30%; difficulty breathing, 25%; pneumonia, 25%; coryza, 24%; influenza-like illness, 22%; bronchitis, 16%; bronchiolitis, 13%; dyspnea, 12%; respiratory failure, 7%; gastrointestinal symptoms, 15%; and neurologic symptoms, 5%. Midgley and colleagues⁷⁸⁰ reviewed 614 US cases in patients admitted to the hospital in 2014 and noted the following: dyspnea, 84%; cough, 81%; wheezing, 70%; and fever, 48%. Fifty-nine percent of these patients were admitted to intensive care units, and 28% received ventilation support. A history of asthma or reactive airway disease was noted in 52%, and these patients were more likely to require care in an intensive care unit. The median age of the patients in this review was 5 years, with an age range from 3 days to 92 years.

Orvedahl and associates⁸⁷⁶ reviewed 139 children at St. Louis Children’s Hospital in St. Louis, Missouri, and reported the following historical findings: fever, 48%; upper respiratory tract symptoms, 96%; difficulty breathing, 80%; wheezing, 67%; and vomiting, diarrhea, or abdominal pain, or a combination, 37%. Physical examination of these patients elicited these findings: fever (temperature $\geq 38^{\circ}\text{C}$), 9%; rhinorrhea, 24%; rash, 8%; tachypnea, 69%; wheezing, 71%; retractions, flaring, grunting, head bobbing, or abdominal breathing, 65%; tachycardia, 42%; delayed capillary refill, 3%; abnormal abdominal examination, 4%; and abnormal neurologic examination, 3%. Treatment in the St. Louis Children’s Hospital patients included the following: oxygen by nasal cannula or face mask, 26%; intravenous fluids, 40%; albuterol, 79%; intravenous or oral antibiotics, 15%; intravenous or oral steroids, 68%; and intravenous magnesium sulfate, 16%.

Neurologic disease has been a significant manifestation of EV D68 infections; this topic is covered later in the neurologic manifestations section of this chapter.*

Pleurodynia (Bornholm Disease)

Epidemic pleurodynia^{54,200,279,422,440,623,796,1067,1146} is an illness that was noted first in 1735 by Hannaeus, a Danish physician.⁴⁵⁵ Not until the late 19th century, however, did the illness receive further attention in the medical literature. At this time, several epidemics in Scandinavian countries were described.^{200,271,354} Although Finsen³⁵⁴ referred to the disease as *pleurodynia*, other investigators who designated outbreaks used geographic names, such as Skien disease, Bamle disease, Drangedal disease, and Bornholm disease, or descriptive names such as epidemic myalgia, devil’s grippé, epidemic diaphragmatic spasm, or epidemic benign pleurisy.⁴²² In 1933, Sylvest¹⁰⁶⁷ published the classic monograph on the subject, and from this publication the name Bornholm disease (from

Bornholm Island, a Danish island in the Baltic Sea) came to be associated with the illness. The enteroviral origin of epidemic pleurodynia was established in 1949.^{270,1155}

Historically, pleurodynia is an epidemic disease, but sporadic cases do occur. A characteristic incubation period of approximately 4 days is followed by the sudden onset of fever and pain. The pain typically is located in the chest or upper part of the abdomen and is muscular in origin and of variable intensity. Occasionally, the pain occurs in other areas of the body. Frequently, the pain is excruciatingly severe and sudden and is associated with profuse sweating, so the patient may appear pale and as though in shock. The pain is spasmodic, with durations varying from a few minutes to several hours. Most commonly, the spasmodic periods last approximately 15 to 30 minutes. During spasms, respirations usually are rapid, shallow, and grunting, suggestive of pneumonia or pleural inflammation. Coughing, sneezing, or deep breathing makes the pain worse. Older children and adults describe the pain as stabbing or knifelike. An older person often fears that a heart attack is occurring.

When pain localizes in the abdomen, it frequently is crampy and suggests colic in a younger child. The child may double over and refuse to walk or move. Occasionally, the abdominal pain in association with a pale, sweaty, shock-like appearance suggests acute intestinal obstruction. Splinting and guarding of the abdomen also lead to consideration of appendicitis and peritonitis.

The fever and pain usually last 1 to 2 days. Frequently, however, the illness is biphasic; after the initial febrile period, the patient is asymptomatic for several days, and then the pain and fever recur. Rarely, patients have several recurrent episodes over the course of several weeks. In these patients, fever is less prominent.

Some degree of tenderness is present in the areas of pain, but frank myositis with muscle swelling is not observed. Pleural friction rubs may be noted on auscultation, and they may appear and disappear with the coming and going of episodes of pain.

In epidemics, both children and adults are afflicted, but most cases occur in persons younger than 30 years of age. Most children have other symptoms of enteroviral infection, such as anorexia, nausea, vomiting, headache, and sore throat. Routine laboratory study is not very helpful. The WBC count varies considerably, but increased percentages of polymorphonuclear neutrophils and band forms are frequent findings. The erythrocyte sedimentation rate also is inconsistent; normal to extremely high values may be observed. The chest radiograph usually is normal.

Complications of pleurodynia seldom develop. Aseptic meningitis has been noted in some patients, and men have experienced orchitis. Cardiac involvement, in the form of myocarditis and pericarditis, also may complicate pleurodynia.

The major etiologic agents in epidemic pleurodynia are coxsackieviruses B3 and B5.^{54,200,523,976,1005,1028} Other viruses associated with epidemic disease include coxsackieviruses B1 and B2 and echoviruses 1 and 6.^{39,200,317} Agents associated with sporadic occurrences of pleurodynia include the following: coxsackieviruses A1, A2, A4, A6, A9, A16, B1, B2, B3, B4, B5, and B6; echoviruses 1, 2, 3, 6, 7, 8, 9, 11, 12, 14, 16, 17, 18, 19, 24, 25, and 30; and PeV 2.^{77,200,260,317,451,590,628,755,796,1065}

Pleurodynia rarely is reported today. Because the EVs that cause pleurodynia still circulate, cases probably are overlooked or misdiagnosed. An outbreak caused by coxsackievirus B1 in football players at a public high school was reported.⁵³⁶ Unfortunately, no clinical data were presented. In 2005, 28 pediatric patients with pleurodynia were observed in a medical center in Northern Taiwan.⁵¹⁷ This outbreak was caused by coxsackievirus B3.

Gastrointestinal Manifestations

Gastrointestinal manifestations occur commonly in enteroviral and parechoviral infections.* Clinical manifestations in addition to vomiting and diarrhea are varied (Table 166.8).

*References 20, 48, 300, 430, 651, 718, 778, 779, 891, 1109, 1118, 1170.

Reye syndrome	2	4	14		1	
Pancreatitis	9	3–5				
Diabetes mellitus		1–5				

Early studies paid particular attention to diarrheal disease in children. However, when specific studies of infantile diarrhea were undertaken, the enteroviral association was far from clear.^{74,200,421,887,1205} The correlation of infection and disease in these studies was compromised by the problem that the main source of culture in study patients and control subjects was from stool; persistent infection in the bowel rendered separation of control subjects and ill patients impossible.

Infections with all coxsackieviruses and echoviruses frequently have one or more gastrointestinal symptoms as part of the general illness. The intensity and spectrum do vary among the specific agents, however, and also among strains of particular viral types. In a review of World Health Organization (WHO) virus reports covering a 4-year period, Assaad and Cockburn⁴² found that the main clinical sign or symptom was gastrointestinal in 12% of coxsackieviral infections and in 6.8% of echoviral infections. In another analysis, Assaad and Borecka⁴¹ noted 16 deaths during the period 1967 to 1975 in patients with coxsackievirus and echovirus infections in whom the principal clinical association was gastrointestinal.

In a 20-year survey in Wisconsin, Nelson and colleagues⁸²⁸ noted that gastrointestinal symptoms occurred in approximately one-third of all patients from whom these investigators recovered nonpolio EVs. Morens and colleagues⁸⁰² reported that in 4% of patients from whom nonpolio EVs were recovered during the 1971 to 1975 period, gastrointestinal disease was the major diagnosis. Horn and coworkers,⁴⁹⁹ studying respiratory viral infections, noted that 21.2% of subjects from whom EVs were recovered had gastrointestinal complaints.

Vomiting

Vomiting is a common manifestation of infection with many coxsackieviral and echoviral types, but it rarely is the major complaint of the patient or the parent.* The frequency of vomiting during outbreaks of illness caused by coxsackieviruses and echoviruses depends on the specific types of virus and on the major manifestation during a particular outbreak. Table 166.9 presents the frequency of vomiting by coxsackieviral and echoviral type. In 14 different enteroviral types, vomiting has been noted as a significant aspect of the illness during disease outbreaks.

Except for coxsackievirus A16 infections (hand-foot-and-mouth disease), in which it is an uncommon complaint, vomiting occurs in approximately 50% of all patients with epidemic enteroviral disease. Vomiting is noted most commonly in meningitis and least commonly in pleurodynia and uncomplicated exanthematous disease.

Diarrhea

Diarrhea occurs commonly in enteroviral, PeV and SAFV infections, but it usually is just one of many manifestations of systemic illness.* Specific studies of diarrheal disease in infants and children have had varied results; some studies indicate an enteroviral origin, whereas others reveal that coxsackieviruses and echoviruses were recovered from well children at the same prevalence.

Ramos-Alvarez and Olarte⁹³¹ carried out an extensive study of diarrheal disease in Mexico City and noted that echoviruses were recovered eight times more frequently from children with diarrhea than from control children without diarrhea. These investigators found that echoviruses 6 and 19 predominated, but types 3, 7, 9, 12, 14, 18, and 21 also were recovered. Pelon and colleagues⁸⁹⁵ noted an association between coxsackieviruses B4 and B5 and acute diarrhea; these investigators observed a 42% coxsackievirus B isolation rate in children with acute diarrhea and a corresponding rate of only 12% in those without diarrhea. Goodwin and associates⁴²¹ noted echoviruses in the stools of children with diarrhea at twice the rate observed in healthy children. In a study by Yow and colleagues,^{1205,1206} no association was found between EVs and infantile diarrhea. Echoviruses were recovered twice as frequently from children ill with diarrhea as from children without gastrointestinal illness.¹²⁰⁶ In Canada, McLean and colleagues⁷⁵³ could find no association between enteroviral infection and gastroenteritis. In a large study of diarrhea in India, coxsackieviruses A9, B3, and B6 and echoviruses 12 and 21 were recovered more commonly from ill patients than from children without diarrhea.⁸²⁰

In several studies of specific diarrhea outbreaks, afflicted persons were noted to be actively infected with a particular virus type. Goldwater⁴¹⁷ observed three children younger than 6 months of age who

	<5	50	Febrile illness, respiratory illness	200
	>5	70		

were infected with echovirus 19 and who had gastroenteritis without other signs or symptoms. Klein and colleagues⁶³⁶ recovered echovirus 11 from the blood of two laboratory workers with acute gastroenteritis. Diarrhea occurred in three of nine volunteers given echovirus 11.¹²⁷ Eichenwald and Kotsevalov³²⁶ and Cramblett and colleagues²⁶⁰ reported epidemic diarrhea caused by echovirus 18 in neonates. An outbreak of diarrhea associated with coxsackievirus A1 was noted in 7 of 14 bone marrow transplant recipients during a 3-week period.¹⁰⁹⁵

Table 166.10 presents the frequency of diarrhea in outbreaks of specific coxsackieviral and echoviral illnesses. Diarrhea varied with regard to the viruses represented and in different studies with the same agents. Diarrhea in enteroviral disease rarely is severe. In most instances, loose stools occur for a 2- to 4-day period. The stools rarely are watery, never are bloody, and at most number six to eight per day. In two child care centers, diarrhea associated with a parechoviral infection occurred in 21% of the children during a one-half-year period.¹¹⁶ The following PeV genotypes have been identified in children with diarrhea: 1, 3, 4, 5, 6, 8, 10, 11.^{900–902,1212} SAFVs have been identified in stool samples from children with diarrhea, but a cause-and-effect relationship has not been established.^{100,459,616,940,1190}

Constipation

Some degree of constipation is a rather frequent occurrence in many acute infectious illnesses, but evaluation is rendered difficult by the subjective nature of the complaint. In coxsackieviral and echoviral diseases, a short period of constipation may be associated with fever, vomiting, and anorexia early in the course of the illness. This period frequently is followed by mild diarrhea.¹²⁷ As noted in Table 166.8, constipation has been reported specifically as a symptom with four coxsackieviral and four echoviral types. Constipation is a particularly common event in children with enteroviral meningitis; it occurs in 10% to 40% of cases.^{200,349,350,597,598,662}

Abdominal Pain

Abdominal pain is a common symptom in many coxsackieviral and echoviral infections. Table 166.11 lists the frequency of occurrence of abdominal pain and the main characteristic of the illness by virus type. Approximately 10% of patients with coxsackievirus A16 hand-foot-and-mouth disease report abdominal pain. In approximately one-fourth of patients, many coxsackieviruses and echoviruses associated with meningitis cause abdominal pain.

TABLE 166.10 Frequency of Diarrhea in Outbreaks of Illness Caused by Coxsackieviruses and Echoviruses

Virus Type	Age Group (y)	Diarrhea (%)	Main Characteristics of Outbreak	References
Coxsackievirus A9	Adults and children	7–100	Fever, rash	200, 690
Coxsackievirus A16	Mainly children	4–33	Hand-foot-and-mouth disease	13, 203, 685, 958
Coxsackievirus B2	Mainly children	9–56	Febrile illness, respiratory illness	200

	<5	12	Meningitis	200
Echovirus 30	>5	5		
	Adults and children	7–10	Meningitis	451, 910, 1092

The magnitude of abdominal pain as a clinical symptom in coxsackieviral and echoviral infections varies considerably. For example, in aseptic meningitis, headache and other neurologic reports overshadow the abdominal symptoms. In other situations, fever and abdominal pain are diagnostically troublesome because of the possible presence of a surgical abdomen (discussed further in the next paragraph). The pain most frequently is periumbilical; it may be either constant or colicky. The fever is most often higher than 38.3°C (101°F).

Peritonitis, Pseudoperitonitis, Appendicitis, Pseudo-obstruction, Mesenteric Adenitis, and Intussusception

Occasionally, coxsackieviruses and echoviruses are associated with illnesses that suggest severe abdominal involvement. Liebman and St. Geme⁶⁹⁸ described two children with abdominal findings suggestive of acute appendicitis (i.e., semirigid, tender abdomen, rebound tenderness, and rectal tenderness) who had associated infections with echoviruses 1 and 14. McLean⁷⁵² described a surgical abdomen in one child with coxsackievirus B1 infection. In this case, virus was recovered from the peritoneal exudate; at surgery, this boy was found to have peritonitis, but his appendix was normal. Thomas¹⁰⁸⁵ reported a 5-year-old boy with coxsackievirus B5 infection who at surgery was found to have

excessive clear peritoneal fluid and markedly enlarged mesenteric lymph nodes. A pregnant woman with acute abdominal pain and rebound tenderness associated with echovirus 8 infection was described.⁸⁹³

In immunofluorescence studies, Tobe¹⁰⁹⁰ showed the presence of coxsackievirus B2 and B5 antigens in the mucous membranes and mesenteric lymph nodes of patients with appendicitis more often than in similar studies in control subjects. He suggested that the viral infection acts as a trigger for appendicitis. Bell and Steyn⁸¹ recovered echoviruses 7 and 9 from the mesenteric lymph nodes of children with intussusception.

Hepatitis

Marked liver involvement is not a rare finding in disseminated coxsackieviral and echoviral infections in neonates.*

The association of hepatitis and enteroviral infection in older children is defined less clearly but probably occurs more commonly than generally realized, on the basis of the number of individual cases reported. Caution

must be exercised in accepting EVs as the exclusive etiologic agents of hepatitis, however, because hepatitis A virus infection was ruled out in only a few of the available older studies.

Morris and associates⁸⁰⁷ described an illness suggestive of a coxsackieviral or echoviral infection in an 18-month-old child who had hyperbilirubinemia and abnormal liver function test results. From this child, coxsackievirus A4 was recovered from blood during the acute illness, and a rise in neutralizing antibody titer to the isolated virus was demonstrated. Chang and Weinstein¹⁸⁶ reported a 3-year-old boy with pharyngitis, urinary abnormalities, and neurologic symptoms who had elevated liver enzyme values (i.e., aspartate transaminase value of 1600 and alanine transaminase value of 1180). Coxsackievirus A9 was recovered from this child's cerebrospinal fluid (CSF), and the child's antibody response to this agent was significant. Coxsackievirus A20 has been associated with clinical hepatitis, and simultaneous infections with coxsackievirus A24 and hepatitis A virus have been demonstrated.¹⁰⁰⁸

An adult with a coxsackievirus B1 infection had both myocarditis and liver involvement.¹⁴ A similar illness caused by coxsackievirus B3 in a 19-year-old woman was described.¹⁰⁶¹ An 11-month-old boy had a Reye-like syndrome in conjunction with coxsackievirus B2 infection.⁶⁰² Reye syndrome has been associated with echovirus 3 infection.⁴⁶⁶ Siegel and colleagues¹⁰²⁸ described a hepatosplenic syndrome in which 15 patients had hepatomegaly and coxsackievirus B5 infection. These patients, most of whom were children, had otherwise typical enteroviral illnesses. Liver function studies were performed in only three instances, and the results were normal.

Echoviruses 1, 3, 4, 6, 7, 9, 11, 14, 20, 21, 25, and 30 have been associated with hepatitis.^{200,525,623,733,796,999,1178,1199} Hepatomegaly occurs commonly in enteroviral infections.^{204,203,347,665,688} During the period from 1971 through 1975, more than 7000 cases of nonpolio enteroviral infection were reported to the Viral Diseases Division at the CDC.⁸⁰¹ In this group were 13 cases of hepatitis and 6 of Reye syndrome; coxsackieviruses A2 and B4 and echoviruses 14 and 22 were associated with Reye syndrome.

Pancreatitis

One of the effects of coxsackievirus B in suckling mice is extensive infection in the pancreas. As with other similarities of infection between suckling mice and human neonates, generalized coxsackievirus B infection in neonates also is accompanied frequently by extensive pancreatic damage. In contrast, pancreatic involvement in older children and adults is not a common occurrence.^{141,816,821,1112} Coxsackieviruses B3, B4, B5, and A9 have been noted. Groeneweg and coworkers⁴⁴¹ described a 3-year-old girl with chronic hereditary pancreatitis associated with a serine protease inhibitor Kazal type 1 gene mutation and a high antibody titer to coxsackievirus type 5.

Diabetes Mellitus

A possible relationship between juvenile diabetes mellitus (DM) and the seasonal occurrence of coxsackievirus B4 was suggested in 1969 by Gamble and Taylor.³⁸⁶ In a second study, Gamble and associates³⁸⁵ noted that titers of coxsackievirus B4 antibodies in patients with type 1 DM within 3 months of the onset of disease were higher than those in physiologically normal subjects or in patients with chronic diabetes.

Since the 1960s, many studies in animal models and children have looked at the relationship between juvenile-onset, type 1 DM and coxsackieviruses B.* Between 1973 and 1984, 10 case-control studies examined the prevalence of antibody to various group B coxsackieviruses in patients with type 1 DM and control subjects. In eight of these studies, the prevalence was greater in the patients with type 1 DM. In three of these studies, IgM antibody to the group B coxsackieviruses was examined, and the prevalence in each was greater in the patients with type 1 DM than in control subjects. A Finnish study noted that patients with type 1 DM were more likely to have IgA antibodies to coxsackievirus B4 than were control subjects.⁵³²

*References 28, 43, 57, 58, 172, 246, 268, 299, 371, 372, 427, 461, 473, 482, 487, 489, 505, 585, 589, 631, 712–714, 877, 1002, 1013, 1088, 1114, 1121, 1171.

Helfand and associates⁴⁷³ performed a well-done case-control study of type 1 DM. These investigators found that new-onset cases of type 1 DM in patients 13 to 18 years of age were more likely than were control subjects to be IgM antibody-positive for 9 of 14 EV serotypes. The serotypes were as follows: coxsackieviruses B2, B3, B4, B5, and B6; coxsackievirus A9; and echoviruses 9, 30, and 34. Green and associates⁴²⁷ in 2004 performed a systematic review of published case-control studies relating to coxsackievirus B serology and type 1 DM. In 13 studies that looked at antibody to all coxsackievirus B types, seven (54%) had significantly more positive antibody values in the cases than in the control subjects. The findings were less impressive when rates of antibody by specific coxsackievirus B serotypes were compared. However, with coxsackievirus B4, the odds ratio was greater than one in 17 (53%) comparisons, and this finding was significant in six (35%) of the studies.

In an extensive study, Skarsvik and colleagues¹⁰³⁵ noted that children with type 1 DM had an impaired type 1 T-cell response against coxsackievirus B4 in contrast to the response in healthy children. The findings led these investigators to suggest that the defect in T-cell function delayed clearance of coxsackievirus B4 and made damage to β cells more likely. In another study involving adults, Varela-Calvino and coworkers¹¹²¹ noted that T-cell proliferative responses against the VP2 protein of coxsackievirus B4 was significantly reduced in patients with type 1 DM, in contrast to the responses in control subjects.

Cudworth and colleagues²⁶⁸ noted a correlation between HLA-BW15 and coxsackieviruses B1, B2, B3, and B4 antibodies in patients with type 1 DM. In 1979, Yoon and colleagues¹²⁰² reported the recovery of coxsackievirus B4 from the pancreas of a previously healthy 10-year-old boy who died after being in a diabetic coma. Hindersson and coworkers⁴⁸⁹ noted the simultaneous onset of type 1 DM in a mother and her 10-year-old son coincident with a coxsackievirus B5 infection.

Clements and coworkers²⁴⁶ noted that 9 of 14 serum samples from children with new-onset type 1 DM were positive for EV RNA by PCR. In contrast, only 4% of serum samples from control children had evidence of EV RNA. Oikarinen and associates⁸⁶⁹ conducted a nested case-control study involving children in Finland who took part in a type 1 DM prediction and prevention study. All case children ($n = 38$) had progressed to clinical type 1 DM. Nondiabetic control children ($n = 140$) were pairwisely matched for sex, birth date, hospital district, and HLA-DP-conferred genetic susceptibility. Serum samples (at 3- to 12-month intervals) were examined for EV RNA. EV RNA-positive samples (5.1%) were significantly more frequent among cases than among control subjects (1.9%). In a more recent study involving children in Finland, Sweden, England, France, and Greece it was noted that antibodies against coxsackievirus B1 were more frequent among diabetic children than among control children.^{792A} In another study from Finland antibody to coxsackievirus B1 was associated with an increased risk of β -cell autoimmunity.⁶⁶⁴ In another Finnish study involving adults, 50% of the patients with type 1 DM had RNA evidence of ongoing enteroviral infection in the gut, whereas none of the control subjects had similar infections.⁸⁷⁰

In a murine model, See and Tilles¹⁰¹³ found that a diabetogenic strain of coxsackievirus B4 infection resulted in persistent detection of viral RNA in the pancreases of most infected mice. This persistence of antigen was associated with chronic islet cell inflammation and elevated islet cell antibody levels. Stimulated peritoneal macrophages caused lysis of islet cells either directly or by an antibody-dependent mechanism. A study in prediabetic children found that the presence of EV RNA in serum was a risk factor for development of β -cell autoimmunity and type 1 DM.⁷¹⁴ Glutamic acid decarboxylase (GAD₆₅) is one of the major β -cell target antigens in the autoimmune β -cell damaging process that leads to the development of type 1 DM.⁷¹² Antibody and cellular immunity cross-reactivity exists between GAD₆₅ and the 2C protein of coxsackievirus B4.^{43,712} The results of several studies suggest that enteroviral infections are associated with the development of β -cell autoimmunity and the eventual destruction of islet cells.^{135,487,713} Time periods from enteroviral infection to the development of β -cell autoimmunity and the eventual development of type 1 DM from β -cell destruction have a great range that perhaps explains the lack of a more specific seasonally related onset of type 1 DM.

A case of neonatal type 1 DM associated with a maternal echovirus 6 infection has been reported.⁸⁷⁷ In Northern Sweden there is a PeV (Ljungan virus) that has been isolated from bank voles.⁸⁴⁴ This virus is a separate species in the PeV genus. It was found that captured bank voles developed diabetes, and they had antibodies to Ljungan virus and autoantibodies against glutamic acid decarboxylase 65 (GADA), islet antigen-2 (IA-2), and insulin (IAA). Antibodies to the Ljungan virus were found in the sera in children in Northern Sweden. Children with type 1 DM had higher antibody values to this virus than were found in nondiabetic control children.

Eye Findings

Acute Hemorrhagic Conjunctivitis

Although conjunctivitis has been a frequent finding in nonpolio enteroviral illnesses since the 1950s, its occurrence as a dominant symptom has been observed only since the 1960s.^{134,182,404,592}

In June 1969, Chatterjee and associates¹⁸⁸ noted an epidemic of acute hemorrhagic conjunctivitis in Accra, Ghana. This disease was nicknamed Apollo 11 disease because it coincided with the time of the Apollo 11 moon landing. Since 1969, many epidemics of acute hemorrhagic conjunctivitis have been described. In most epidemics, EV 70 has been the etiologic agent, but similar epidemics have been caused by a variant of coxsackievirus A24.²³⁹ More recently, this virus has been the cause of more epidemics than has EV 70.* Most epidemics have occurred in tropical and semitropical countries; however, outbreaks have been observed in Minnesota, as well as in Moscow, London, and other European cities.^{661,1198} In the continental United States, epidemic disease has occurred in Florida and North Carolina.¹⁵³ During epidemics, all age groups are affected, but the highest attack rate is in school-age children.¹¹⁴⁸

Acute hemorrhagic conjunctivitis has a sudden onset, with severe eye pain and associated photophobia, blurred vision, lacrimation, erythema, and congestion of the eye, as well as edema and chemosis of the lids.⁴⁸³ Subconjunctival hemorrhages of varying size, frequently transient punctate epithelial keratitis, conjunctival follicles, and preauricular lymphadenopathy are present. The eye discharge initially is serous but becomes mucopurulent with secondary bacterial infection. Systemic symptoms, including fever, are rare manifestations. Within 2 to 3 days after the onset of illness, patients note some improvement, and recovery is usually complete in 7 to 12 days. In a study in American Samoa, researchers found that illness caused by coxsackievirus A24 was somewhat different from that caused by EV 70.⁹⁹⁵ In cases caused by coxsackievirus A24, conjunctival hemorrhage was less severe, and upper respiratory and systemic symptoms occurred more frequently. In a study in American Samoa of disease caused by EV 70, researchers found that children 2 to 10 years of age had the highest attack rate, and antibody from previous infection gave only partial protection against symptomatic reinfection.⁹⁶

Occasionally, findings suggestive of pharyngoconjunctival fever have been noted. A few patients have had a poliomyelitis-like illness or polyradiculomyeloneuropathy after EV 70 acute hemorrhagic conjunctivitis.^{529,1135} Epidemics are explosive, with spread mainly by the eye-hand-fomite-eye route.

Conjunctivitis Associated With Other Enteroviral Illness

Conjunctivitis is a common minor manifestation of enteroviral illness with several specific agents. Table 166.12 presents the frequency of occurrence of conjunctivitis in selected outbreaks of disease caused by coxsackieviruses and echoviruses. Conjunctivitis was most prevalent in coxsackievirus B3 and B5 and echovirus 9 and 30 infections. In addition to the outbreaks reported in Table 166.12, conjunctivitis has been noted in isolated illnesses associated with echoviruses 1, 6, and 20.⁶²³

Photophobia

As would be expected, photophobia occurs commonly in aseptic meningitis caused by coxsackieviruses and echoviruses. During epidemic

Coxsackievirus A16	Mainly children	0–18	Hand-foot-and-mouth disease	188, 728, 954
Coxsackievirus B2	Mainly children	2	Nonspecific febrile illness, respiratory illness	200
Coxsackievirus B3	Children	2–42	Upper respiratory illness	200
Coxsackievirus B4	Children	25	Upper respiratory illness	200
Coxsackievirus B5	Mainly children	7–50	Rash, meningitis, hepatosplenic illness, respiratory illness, pleurodynia	210, 260, 976, 991
Echovirus 2	Children	25	Rhinorrhea	200
Echovirus 4	Children	Rare	Meningitis	733
Echovirus 9	Mainly children	13–30	Rash, meningitis	154, 200, 981
Echovirus 11	Children	15	Rash	210
Echovirus 16	Children	6–10	Rash	450, 832
Echovirus 30	Mainly children	10–60	Meningitis, nonspecific febrile illness	200, 451, 1092

meningitis, researchers have noted it with the following viruses: coxsackievirus A9 and echoviruses 3, 4, 6, 7, 9, 19, and 30.* It is a most common occurrence with echovirus 9 and 30 infections, but the incidence of this complaint varies greatly in different reports. In one echovirus 30 outbreak, 80% of the patients studied had photophobia.¹⁰⁹² On average, 20% of patients with meningitis have remarkable photophobia. Photophobia also is associated with pleurodynia caused by coxsackievirus B infections.^{976,1146}

Other Eye Findings

Nodular lesions on the palpebral conjunctiva were observed in some patients with coxsackievirus A10 infection and lymphonodular pharyngitis.¹⁰⁴⁹ A corneal ulcer occurred in one patient with hand-foot-and-mouth disease.⁷²⁸ Optic neuritis was described in a boy with pleurodynia, although the enteroviral origin of the illness was not confirmed in the laboratory.¹¹⁰⁷ Keratoconjunctivitis was noted in two boys with echovirus 13 infections.⁶³⁰ Periorbital edema was observed in one patient with echovirus 9 meningitis. A woman with panuveitis associated with coxsackievirus B3 infection was described.³⁶¹ One report detailed monofocal outer retinitis in a 36-year-old man with hand-foot-and-mouth disease.⁴⁴⁵ Five extensive outbreaks of uveitis caused by echoviruses 11 and 19 in hospitalized young children were noted in three Siberian cities.¹¹²² These cases occurred predominately in infants hospitalized for other illnesses such as bronchitis, pneumonia, gastroenteritis, sepsis, dystrophy, and premature birth. Three normal adult patients with anterior uveitis in whom PeV was identified in ocular fluid have been noted.²⁸⁷ In the same study an adult positive for human immunodeficiency virus (HIV) had panuveitis. Sore eyes and other unspecified eye complaints also have been noted frequently in patients with coxsackieviral and echoviral infections.^{200,343,359,444,678,727,830,993,1000}

Cardiovascular Manifestations

Pericarditis, Myocarditis, and Dilated Cardiomyopathy

Pericarditis or myocarditis or both have been noted in association with 27 different nonpolio EVs. The relative importance of the different serotypes is presented in Table 166.13. The group B coxsackieviruses have been implicated most frequently in heart disease. Coxsackievirus B5 has been the most common causative agent, but types 2, 3, and 4 also have been reported frequently. Of the echoviruses, type 6 has been associated most often with cardiac involvement, but the clinical findings with this agent have been described in only a few cases.

In patients with coxsackievirus B cardiac disease, hepatitis, pneumonia, nephritis, meningitis, and orchitis have been occasional associated findings. In 2007 to 2008, severe neonatal disease (often with myocarditis) associated with coxsackievirus B1 infection was detected.^{167,879,1164} These

severe cases were caused by a single genetic lineage. Sometimes, arrhythmias are the only clinical manifestations of myocarditis.^{206,1106} Constrictive pericarditis occurs occasionally.⁷⁴⁶ The mortality rate for acute coxsackieviral and echoviral heart disease is unknown, but it is significant. Unfortunately, proper virologic study rarely is performed in nonfatal disease. In the only published follow-up study, researchers found that patients who survived acute coxsackievirus myocarditis usually recovered completely, without any residual disability.¹⁰⁵⁹

The early descriptions of coxsackievirus B infection with myocarditis in the 1950s and early 1960s indicated acute, usually fulminant illnesses in which a coxsackievirus B serotype could be recovered from multiple sites, such as the throat, stool, and CSF, as well as from the heart and other organs at autopsy.^{398,438,622,624,1115} Group B coxsackieviruses originally were isolated from suckling mice, and the infection in these mice caused acute, overwhelming fatal infections involving multiple organs, including the heart.^{279,576} Coxsackievirus B infections in mice were studied in mouse model systems in the 1950s and 1960s, and researchers found that infections in older mice were affected markedly by the virus strain, mouse genetics, and drugs.^{106,511,629} Since the 1970s, studies in mouse model systems have become more sophisticated, but they still depend on specific coxsackievirus B strains and specific mouse strains.*

More recent studies in mouse model systems noted the progression of acute coxsackievirus B infection to chronic infection and cardiomyopathy.^{26,492,588,744,925,942} Since the mid-1980s, acute, subacute, and chronic cardiomyopathy has been studied in patients by antigen-detection techniques and newer serologic methods.[†]

Bowles and colleagues¹¹³ found coxsackievirus B nucleic acid sequences in myocardial biopsy samples from several patients with cardiomyopathy. Muir and colleagues⁸¹³ detected EV-specific IgM antibodies in the sera of nine patients with chronic relapsing pericarditis. Fujioka and coworkers³⁷⁷ reported positive enteroviral PCR results from endomyocardial biopsy specimens in 6 of 31 patients (19%) with dilated cardiomyopathy (DCM). Andréoletti and collaborators²⁹ noted EV RNA in 18 of 25 samples from the heart tissue of patients with DCM or ischemic cardiomyopathy. However, in two other well-controlled studies, enteroviral RNA could not be identified in endomyocardial biopsy samples or in heart tissue from patients undergoing heart transplantation.^{251,699} In 1994, Muir and Archard⁸¹⁰ and Melchers and associates⁷⁶⁵ reviewed the evidence for persistent enteroviral infection in chronic medical conditions, including idiopathic DCM. Muir and Archard⁸¹⁰ concluded that persistent enteroviral infection is associated causally with chronic medical

conditions, whereas Melchers and colleagues⁷⁶⁵ found no clear evidence for enteroviral persistence and the subsequent development of chronic medical conditions.

Since the mid-1990s, additional studies in humans have been performed, with mixed results with regard to the role of coxsackievirus B in the origin of chronic cardiomyopathy. Bowles and associates¹¹² studied cardiac samples for PCR analysis from 624 patients of all ages with myocarditis and 149 patients with DCM. Enteroviral genome was found in the cardiac samples of 85 patients with myocarditis and in the samples from 12 patients with DCM. The histopathologic findings in nine of these 12 patients demonstrated borderline or mild findings of inflammatory infiltrates. Another study by investigators in the same group examined 80 explanted hearts from children with end-stage heart disease, and an enteroviral genome was not detected.³⁶⁷ In another study, Zhang and coworkers¹²¹⁴ found evidence of enteroviral capsid protein VP1 by immunohistochemical staining in 47 of 89 patients with DCM. In a study performed in Japan, Fujioka and associates³⁷⁶ detected EV RNA in 7 of 30 American patients (23%) and in 15 of 47 Japanese patients (32%) with DCM. In our opinion, the data in these studies suggest that EVs have a role in some patients with DCM.

The general theme in most contemporary mouse model studies is that damage to the myocardium is not caused by the direct cytopathic effect of the virus, but rather it is caused by the cellular immune response of the host. Unfortunately, the mouse model data and the less than definitive data from human studies have led cardiologists and others to think that the model systems are representative of human disease.^{348,710} No adequate follow-up studies of survivors of acute enteroviral myocarditis or pericarditis have been conducted. Levi and colleagues⁶⁹⁰ compared follow-up cardiac data on 10 adults who had acute myocarditis associated with coxsackieviral infections 42 to 68 months previously with similar cardiac data from normal age- and sex-matched subjects. No statistically significant differences in the two groups were found in the seven tests evaluated.

Orinius⁸⁷⁵ performed cardiac examinations on 53 adults who had coxsackievirus B infections 2 to 11 years previously. The initial diagnoses in these 53 patients were meningitis in 33 cases, encephalitis in three cases, pleurodynia in six cases, pericarditis in two cases, and nonspecific complaints in 9 cases. Of this group, the "possibility of cardiomyopathy was established" in two (4%) cases. Two patients who previously had pericarditis were normal at follow-up.

Sainani and associates⁹⁸² performed follow-up studies on 20 adults and two teenagers who had coxsackievirus B myocarditis or pericarditis and found that five (23%) patients had chronic heart failure. Unfortunately, the duration of time since the primary illness of the patients was not reported.

Bergström and colleagues⁹¹ performed follow-up examinations on five patients (two teenagers and three adults) who had had enteroviral myopericarditis and found that none had significant symptoms or physical signs. No follow-up data are available for neonates, infants, and children who have had enteroviral myocarditis.

In 1954, Stürup¹⁰⁵⁹ reported a follow-up study of patients admitted to the hospital in 1930 to 1932 with pleurodynia. Of nine patients evaluated, including four who had a history of acute pericarditis, none had constructive pericarditis.

Other Cardiac Manifestations

Numerous investigators have studied the possible association of coxsackievirus B infection and myocardial infarction.* In many instances, patients with infarction have been demonstrated to have concomitant coxsackievirus B infection.^{328,431,438,674,675,834,843,856,1181,1184} In controlled studies, the results have varied. Nikoskelainen and associates⁸⁴³ noted that nine of 59 patients with acute myocardial infarction had coxsackievirus B infection, whereas in the control group of 38 patients without infarction, only one patient had evidence of infection. Similarly, Nicholls and Thomas⁸³⁴ found that 26% of patients had infections, but no infections were found in the control subjects.

In contrast, five other studies failed to show an increased rate of infection in patients with myocardial infarction, in contrast to control subjects.^{431,438,856,912,1181} However, two of these studies were performed during a nonenteroviral season,^{912,1181} and in a third study, little coxsackievirus B activity occurred in the community during the study period.⁴³¹ Analysis of the available studies indicates that coxsackievirus B infection would appear to have a role in myocardial infarction. In one coxsackievirus B5 infection, inferolateral wall myocardial necrosis occurred, but coronary arteriography did not demonstrate obstruction.²⁹³

Chandy and associates¹⁷⁷ presented data in which antibody to group B coxsackieviruses was related to rheumatic-like valvular heart disease, and Burch and associates¹³⁰ demonstrated coxsackievirus B antigens in rheumatic lesions of the heart. Limson and colleagues⁷⁰⁰ could find no association between group B coxsackieviruses and rheumatic fever. Soboleva and associates¹⁰³⁹ noted an association between coxsackievirus A13 and rheumatic fever; these investigators reported seven children with concomitant streptococcal and coxsackievirus A13 infection. Children with fulminant EV 71 infection have been noted to have acute left ventricular dysfunction.^{176,183,516} A 27-month-old girl who died suddenly was found to have SAFV identified in the CSF, blood, and myocardium.⁸³⁶

A 4-month-old boy who had repair of an atrioventricular septal defect was found to have a coxsackievirus B2 endocarditis.¹⁰² This virus was recovered from the excised prosthetic patch.

Genitourinary Manifestations

Orchitis and Epididymitis

Group B coxsackieviruses are second only to mumps as causative agents of orchitis.^{39,200,258,369,440,623,802,1011,1065,1158} Coxsackievirus B5 is the virus associated most commonly with this disease, although coxsackieviruses B2 and B4 also have been implicated on many occasions. In almost all instances, orchitis is a secondary event in enteroviral infections. The most common association is with pleurodynia. The illness frequently is biphasic: fever and pleurodynia develop initially, and then apparent recovery is followed by orchitis approximately 2 weeks after onset. Many patients also have epididymitis. In epidemics of disease caused by group B coxsackieviruses, the occurrence of testicular involvement varies considerably. Generally, orchitis occurs infrequently, but in one outbreak of coxsackievirus B2, 17% of postpubertal male patients had orchitis, and 7% also had epididymitis.²⁰⁰ Orchitis also is associated frequently with pericarditis and myocarditis. In one instance, coxsackievirus B5 was recovered from a testicular biopsy specimen.²⁵⁸

In virtually all instances, testicular involvement has occurred in postpubertal patients, mostly in young adults. In addition to coxsackieviruses B2, B4, and B5, other EVs have been implicated: coxsackieviruses B1 and B3^{200,623} and echoviruses 6, 9, and 11.^{623,1156} Meningitis and exanthem have been associated with orchitis.

Nephritis

Scattered cases of nephritis associated with nonpolio enteroviral infections have been reported. Bayatpour and colleagues⁷⁰ noted acute glomerulonephritis in a 9-year-old boy with an extensive coxsackievirus B4 infection. This child had a concomitant rise in antistreptolysin O titer. Yuceoglu and associates¹²⁰⁷ reported twins with echovirus 9 infection and acute glomerulonephritis; Burch and Colcolough¹²⁸ observed a patient with progressive fatal pancarditis and nephritis in whom coxsackievirus B4 antigen was found in the kidneys. Mesangiolytic glomerulonephritis associated with an echovirus 6 infection was described in an infant with immune deficiency.⁵²⁰

Other Genitourinary Findings

Hemolytic-uremic syndrome has been associated with virologic or serologic evidence of infection with the following: coxsackieviruses A2, A4, A9, A10, A16, A21 and B1 to B6; echoviruses 4, 6, and 7; and PeV 1.^{44,290,406,857,938,939} De Petris and colleagues²⁹⁰ demonstrated titer rises to various EVs in patients with hemolytic-uremic syndrome who tested positive or negative for infections with verocytotoxin-producing *Escherichia coli*. Other abnormal renal or urinary findings in nonpolio enteroviral infections include the following: acute oliguric renal failure

*References 328, 431, 438, 674, 675, 834, 843, 856, 912, 1181, 1184.

with coxsackievirus B5³⁸; pyuria, hematuria, or proteinuria with echoviruses 1, 6, and 9 and coxsackievirus B5^{200,598,685,981,1000}; and hemorrhagic cystitis.⁸⁰² A 7-year-old girl with coxsackievirus A10 infection had vaginal ulcerative lesions,⁷⁸⁷ and Wassermann test results have been falsely positive in patients with echovirus 9 and coxsackievirus B5 infections.⁹²⁴

Hematologic Findings

In 1968, Horwitz and Moore⁵⁰⁶ described an outbreak of infectious lymphocytosis during which 27 mentally handicapped children were studied. The mean WBC count of the study group patients was 57,200; lymphocytes accounted for at least 50% of the total in all cases. Approximately one-half of the patients had low-grade fever, and 15 of 27 had moderate diarrhea. A nontypeable EV suggestive of coxsackievirus group A was recovered from the ill patients, and neutralizing antibody to a strain (EVU-16) of the isolated virus developed in 31% of the patients in whom serologic studies were performed.^{442,506}

Letsas and colleagues⁶⁸⁹ reported a 17-year-old-boy with fulminant myocarditis and hemophagocytic syndrome. Over the course of a 3-day period, his hematocrit decreased from 40.9% to 31.7%, and his platelet count went from 90,000 to 38,000/mm³. Examination of the bone marrow revealed many mature histiocytes with active hemophagocytosis. The patient improved dramatically with inotropic and intravenous immunoglobulin (IVIG) treatment. Katsibardi and coworkers⁶⁰⁰ reported the occurrence of hemophagocytic syndrome associated with enteroviral infections in three children with malignant diseases; in spite of IVIG and pleconaril treatment, all cases had a fatal outcome.

Muscle and Joint Manifestations

Arthritis

During the period from 1971 to 1975, during which EVs were recovered from 7075 persons in the United States, nine instances of rheumatic disease were reported⁸⁰²; although not clearly specified, three patients apparently had arthritis. Blotzer and Myers¹⁰¹ noted an adult with echovirus 9 infection and the concomitant onset of arthritis that persisted for 3 months. Echovirus 9 was recovered from the synovial fluid of a man with acute monocytic arthritis,⁶⁵⁶ and one adult and one adolescent had serologic evidence of coxsackievirus B4 infection in association with the onset of rheumatoid arthritis-like illness.⁵³¹

Myositis

Because group A coxsackieviruses routinely cause myositis in suckling mice, a reasonable approach is to suspect a similar clinical manifestation in people. Myalgia also is a common complaint in illnesses caused by many coxsackieviruses and echoviruses.^{39,200,369,451,663,755} However, almost no direct (i.e., demonstration of virus in muscle) or indirect (i.e., elevations in muscle enzymes) evidence of muscle involvement in routine enteroviral illnesses exists. Of the nine patients with rheumatic disease described by Morens and colleagues,⁸⁰² six apparently had myositis; in one instance, coxsackievirus A2 was implicated, and in another patient with polymyositis, coxsackievirus A9 was the related agent. Three patients with echovirus 18 infection and polymyositis have been reported.⁶¹⁰ Acute rhabdomyolysis in one adult and myositis, myoglobinemia, and myoglobinuria in another adult have been associated with echovirus 9 infection.^{564,582} Christensen and associates²³⁷ noted that children with dermatomyositis were more likely to have serum antibody to one or more group B coxsackieviruses than were control children. Chou and Gutmann²³³ noted EV-like particles in the muscles of two patients with fatal dermatomyositis; Tang and colleagues¹⁰⁷⁶ demonstrated coxsackievirus A9 in the muscles of an 11-year-old girl with chronic myopathy. Using both PCR and dot-blot hybridization assays, Fox and colleagues³⁶⁴ could not find evidence of persistent enteroviral infection in 32 adults with inflammatory muscle disease (one patient with dermatomyositis and 31 patients with polymyositis).

Yousef and coworkers¹²⁰⁴ reported EV RNA in biopsy specimens from six of 13 patients (46%) with idiopathic polymyositis or dermatomyositis but in no samples from 13 patients with other muscle disorders. Behan and associates⁷² looked for picornavirus RNA in biopsy specimens from 41 patients with inflammatory myopathy, but all results were negative.

Dekel and associates²⁸⁸ reported a 4-year-old girl with localized thigh swelling caused by coxsackievirus A21. On muscle biopsy, perivascular infiltrates were noted, but the muscle fibers were not affected. Widespread edema was found in the muscle.

Skin Manifestations

Nonpolio EVs as a group are a common cause of a variety of skin manifestations.^{197,1159,1162} In the summer and fall, these viruses are the leading causes of exanthems. Variation in the clinical expression rate of exanthem and in the age of the host is marked among the various viral types. In general, dermatologic expression is related inversely to the age of the infected patient. The frequency of exanthem and common associated illnesses by viral type are presented in Table 166.14.

Coxsackievirus A2

Rash associated with coxsackievirus A2 has occurred rarely. Febrile illness with exanthem in conjunction with coxsackievirus A2 infection was observed in Cincinnati in 1957; no details of this outbreak were presented.⁹⁷⁸ Assaad and Cockburn⁴² reviewed approximately 15,000 enteroviral illnesses for the period from 1967 to 1970 that were reported to the WHO and noted that in 45 instances, skin or mucous membrane lesions associated with coxsackievirus A2 infection were the main clinical manifestations.

Coxsackievirus A3

One case was reported, but no details are available.⁷⁹⁶

Coxsackievirus A4

Exanthem has been noted infrequently with coxsackievirus A4 infection.^{42,204,360,807,1211} However, many cases may be missed because this virus grows poorly in tissue culture, and suckling mouse inoculation rarely is used in diagnostic laboratories. Six children were observed in one outbreak.³⁶⁰ All patients initially had herpangina, and then the exanthem appeared concurrently with or after defervescence. It initially was erythematous, maculopapular, and discrete. In some children, the rash resolved within 4 days, but in others it progressed and became vesicular. The vesicular lesions occurred in crops, spread to the extremities, but not the palms and soles, and were yellowish, opaque, and 5 to 10 mm in size. They persisted for 1 to 2 weeks and regressed, with a brownish discoloration. The lesions easily were confused with resolving bug bites. Other manifestations of coxsackievirus A4 infection include an exanthem suggesting combined scarlet fever and rubella,³⁹⁷ a maculopapular rash that clears with desquamation,⁸⁰⁷ and an anaphylactoid, purpura-like rash (Fig. 166.8).²⁰⁴

Coxsackievirus A5

During the 4-year period studied by Assaad and Cockburn,⁴² coxsackievirus A5 was second only to coxsackievirus A16 in the number of instances for which exanthem or mucous membrane involvement was the main clinical manifestation. Even with this apparent frequency, most instances of exanthem have been sporadic rather than part of an outbreak of exanthematous disease. The most common finding is hand-foot-and-mouth disease, which is not clinically discernible from that caused by coxsackievirus A16.^{267,356,360} In one patient, the virus was recovered from vesicular fluid.³⁵⁶

Coxsackievirus A6

In the present decade, severe hand-foot-and-mouth disease has been found in coxsackievirus A6 outbreaks in the United States, Taiwan, Finland, Japan, Singapore, New Zealand, China, and the United Kingdom.* Rash and fever were more severe, and hospitalization was more common than that seen in coxsackievirus A16 hand-foot-and-mouth syndrome cases. In the United States, there were 63 cases noted between November 7, 2011 and February 29, 2012.¹⁴⁷ In California, cases continued to occur in the spring and summer of 2012 (C. Glaser, Department of Public Health, California, personal communication, 2013). The rash in coxsackievirus A6 hand-foot-and-mouth disease is

FIG. 166.8 Erythematous, papular, papulovesicular, and petechial lesions suggestive of anaphylactic purpura in a child with coxsackievirus A4 infection.

FIG. 166.9 Papular-urticarial lesions in coxsackievirus A9 infection. (From Cherry JD. Newer viral exanthems. *Adv Pediatr*. 1969;16:233–86.)

different (“atypical”) from that seen in coxsackievirus A16 and EV 71 infections. In a review of 80 patients it was noted that 99% had a vesicubullous and erosive eruption.⁷⁴² In 55% of the patients, the rash was accentuated in areas of eczematous dermatitis (“eczema coxsackium”). The rash involved more than 10% of the body surface area in 61% of the patients. In 37% of the patients the exanthem was Gianotti-Crosti-like; 17% of the patients had petechial or purpuric lesions. Some of the patients had delayed cutaneous findings including desquamation of the palms and soles and onychomadesis and Beau lines. In the summer of 2015, Banta and colleagues⁶⁰ noted an outbreak of coxsackievirus A6 hand-foot-and-mouth disease in 53 military basic trainees at Lockland Air Force Base in Texas. In association with a coxsackievirus A6 outbreak in Marseille, France in 2013 there was an outbreak of osteoarticular infections with *Kingella kingae* in a day care facility involving five toddlers.³²⁹ It was suggested that the enteroviral infections triggered the *K. kingae* outbreak.

Coxsackievirus A7

Coxsackievirus A7 was recovered from one child with a morbilliform rash and aseptic meningitis.⁴³⁴ An adult with a fatal coxsackievirus 7 infection had pancarditis, pneumonia, and hand-foot-and-mouth disease.⁵⁵

Coxsackievirus A9

Coxsackievirus A9 is a common cause of exanthem (Figs. 166.9 and 166.10).^{*} In contrast to coxsackievirus A16 and echovirus 9, in which rates of clinical exanthem expression are high, the rate of skin manifestations in coxsackievirus A9 infection is low. A review of 259 coxsackievirus A9 infections in 1970 revealed an exanthem rate of 4%.²⁰⁰ Most cases of coxsackievirus A9 exanthem occur sporadically, although a few outbreaks have been described.^{208,686,853}

Skin manifestations in coxsackievirus A9 infection have been interesting and varied. The most common rash illness is characterized by fever and an erythematous, maculopapular rash that starts on the face and neck and spreads to the trunk and extremities. Aseptic meningitis is a common associated finding.

In 1960, Lerner and colleagues⁶⁸⁸ reported on 11 children with exanthem associated with coxsackievirus A9 infection. Of the patients, six had vesicular lesions and two patients had associated viral pneumonia. Since 1960, vesicular exanthem has been noted on several occasions.^{200,208,524} Most commonly, illnesses have been described as hand-foot-and-mouth disease, but when the reports were analyzed, the rashes were vesicular but not always in a peripheral pattern.

Papular urticaria and large urticarial lesions have been occasional manifestations of coxsackievirus A9 infection (see Fig. 166.9).^{204,208} Other manifestations include Stevens-Johnson syndrome and a severe illness simulating meningococcemia (see Fig. 166.10).^{204,802}

FIG. 166.10 Petechial and purpuric rash in a child with coxsackievirus A9 infection.

Coxsackievirus A10

The most common exanthematous illness associated with coxsackievirus A10 infection is hand-foot-and-mouth disease.^{131,200,244,315,549,691} Stevens-Johnson syndrome was associated with coxsackievirus A10 infection in one instance,²⁰⁰ and a child with ulcerative genital lesions also was reported.⁷⁸⁷

Coxsackievirus A16

In the WHO review of enteroviral infections for the 4-year period from 1967 through 1970, coxsackievirus A16 was associated with almost one-half of all skin or mucous membrane diseases. Coxsackievirus A16 is the major cause of hand-foot-and-mouth disease (Figs. 166.11 through 166.14). Of historical interest is that hand-foot-and-mouth disease apparently was a new clinical entity in 1956.⁸⁵² It was noted in sporadic outbreaks until approximately 1963, and since that time it has been a regularly recurring disease throughout the world.* Serologic data suggest that coxsackievirus A16 was not in wide circulation until approximately 1963.²⁰³

The signs and symptoms of coxsackievirus A16 hand-foot-and-mouth disease are recorded in Table 166.15. All illnesses have a typically enteroviral pattern with a short incubation period (4–6 days) and a summer and fall seasonal pattern. The clinical expression rate of the exanthem-exanthem complex is high—close to 100% in young children, 38% in schoolchildren, and 11% in adults.⁸⁰³ Exanthem occurs more commonly in children, but in adults, the rash occurs more frequently

FIG. 166.13 Two large ulcerative lesions on the underside of the tongue in a patient with hand-foot-and-mouth disease caused by coxsackievirus A16.

with coxsackievirus A16 than with any of the other enteroviral agents.

Illness is ushered in with a mild prodromal fever, anorexia, malaise, and frequently a sore mouth. Enanthem occurs 1 to 2 days after the onset of fever, and the exanthem appears shortly thereafter. Of the

cutaneous lesions, oral lesions are present more consistently than lesions of the skin. Because of this prevalence, illness, particularly in adults, is identified mistakenly as aphthous stomatitis (canker sores) or herpes simplex virus (HSV) infection. The intraoral lesions are ulcerative and average approximately 4 to 8 mm. The tongue and buccal mucosa are involved most frequently.

As noted in Table 166.15, the hands are involved more commonly than the feet. Buttock lesions also occur frequently, but they usually do not progress to vesiculation. The lesions on the hands and feet generally are vesicular and vary in size from 3 to 7 mm; they typically occur more commonly on the dorsal surfaces but frequently on the palms and soles, as well. The vesicles contain virus, but cytologic examination usually does not reveal diagnostic findings. These lesions clear by absorption of the fluid in approximately 1 week.

Of considerable interest is the frequent association of coxsackievirus A16 with subacute, chronic, and recurring skin lesions.^{340,826} Evans and

Waddington³⁴⁰ described an 84-year-old woman with chronic recurring skin lesions of more than 2 years' duration. Nankervis and associates⁸²⁶ noted both subacute and recurring lesions in children. Higgins and Crow⁴⁸⁴ reported a 31-year-old woman with Darier disease who had a Kaposi varicelliform eruption caused by coxsackievirus A16, and a similar illness was noted in a 1-year-old boy with eczema.⁸¹⁹ One child with a Gianotti-Crosti-like eruption (papular acrodermatitis of childhood) associated with coxsackievirus A16 infection was described.⁵⁵⁹

Coxsackievirus B1

Exanthem occasionally occurs in coxsackievirus B1 infections.^{42,200,204,202,286,723} The most common cutaneous finding is an erythematous maculopapular eruption that is discrete. Two children with illnesses suggestive of hand-foot-and-mouth disease have been observed.²⁰⁴

Coxsackievirus B2

Coxsackievirus B2-associated exanthem is a rare occurrence. Maculopapular, vesicular, and petechial lesions have been noted.^{39,42,360}

Coxsackievirus B3

Exanthem occasionally is reported as a sporadic event in coxsackievirus B3 infections, and a small outbreak occurred in one instance.^{39,42,139,256,349,458,523,686,1208} Erythematous maculopapular eruptions occur most commonly, but petechial rash illnesses suggestive of meningococcemia also have been observed. Hand-foot-and-mouth disease was reported in one child,⁶⁸⁶ and another child had a more generalized vesicular eruption. An adult with recurrent hand-foot-and-mouth disease had a rise in neutralizing antibody titer to coxsackievirus B3.²⁵⁶

Coxsackievirus B4

Although cutaneous manifestations with coxsackievirus B4 were noted as frequently as were those associated with coxsackieviruses B1, B2, and B3,^{42,200} few clinical descriptions exist.^{597,625} Morbilliform, petechial, and urticarial rashes have been described.

Coxsackievirus B5

Of the group B coxsackieviruses, type B5 is noted most frequently to have skin manifestations.* The rash usually is maculopapular; petechial lesions are observed occasionally, and one child with urticaria was reported.²⁰⁹ Several children studied by Cherry and colleagues²⁰⁹ had a roseola-like illness pattern. During outbreaks of coxsackievirus B5 illness, approximately 10% of young children have an exanthem. Many patients have concomitant aseptic meningitis. One adult patient with recurrent hand-foot-and-mouth disease had serologic evidence of coxsackievirus B5 infection.

Coxsackievirus B6

Goldwater⁴¹⁸ identified 97 children and adults with coxsackievirus B6 infection. The most prominent finding in these cases was cough and pneumonia. Twenty patients had exanthems; the rash was morbilliform and was associated with high fever and cough.

Echovirus 1

Exanthem and conjunctivitis have been associated with echovirus 1 infection in several children.⁷⁴⁷

Echovirus 2

Exanthem occasionally occurs with echovirus 2 infection.^{200,981,1047} The rash has been erythematous macular in some instances but usually is maculopapular and discrete. Most children have had associated fever and pharyngitis.

Echovirus 3

Exanthem was noted in 2 of 29 children with echovirus 3 infection.⁴⁶⁶ In both instances, the rashes were petechial; most patients in this outbreak

Data from references 89, 283, 344, 357, 384, 560, 662, 682, 972, 1040, 1162 and Cherry JD. Newer viral exanthems. *Adv Pediatr*. 1969;16:233–86.

had aseptic meningitis. Details of other echovirus 3 infections and exanthems are lacking.^{42,502}

Echovirus 4

Echovirus 4 is a common cause of epidemic aseptic meningitis, and exanthem is an associated finding in 10% to 20% of pediatric cases.^{204,358,383,597,678,733,845,937,1043} The rash usually is macular or maculopapular, has its onset 1 to 3 days after the initial fever, and lasts 1 to 2 days. A child with a petechial rash was noted.⁵⁹⁷

Echovirus 5

One major outbreak of echovirus 5 infection with exanthem was described.⁴⁰² This outbreak, which involved a maternity unit, resulted in a macular rash in 36% of the infants and 14% of the mothers. The rash was most prominent on the limbs and buttocks, appeared 24 to 36 hours after the onset of fever, and lasted 2 days. Selwyn and Howitt¹⁰¹⁹ reported a child who had a macular rash with a zoster distribution. A neonate with sepsis-like illness and exanthem was described.⁴⁴⁷

Echovirus 6

Although echovirus 6 has been one of the more prevalent EVs since the late 1970s, it has been associated only sporadically with exanthematous disease. The following manifestations have been observed: morbilliform,¹¹²⁸ maculopapular,^{754,1173} macular,⁷⁴⁰ and papulopustular exanthems⁵⁹⁸; Stevens-Johnson syndrome¹¹³²; and pityriasis rosea in an adult and a child.⁵⁹⁸ Meade and Chang⁷⁶⁰ reported an interesting zoster-like eruption in a 7-year-old boy in whom echovirus 6 was recovered from several bullae.

Echovirus 7

Echovirus 7 has been associated occasionally with exanthem.^{42,272,562,796} In one outbreak of aseptic meningitis, five of 13 patients had erythematous maculopapular rashes that occurred during fever.⁵⁶² One child with a discrete maculopapular rash and thrombocytopenia was described.⁷⁴⁷ The case of a 37-year-old woman with echovirus 7 infection, leukocytoclastic vasculitis, and palpable purpura was reported.²¹⁸

Echovirus 9

Since the 1960s, echovirus 9 has been the most prevalent nonpolio EV, and exanthem is a common clinical manifestation (Table 166.16, Fig. 166.15).^{*} Nonspecific febrile illness and aseptic meningitis are the usual

*References 42, 109, 200, 209, 256, 292, 444, 469, 847, 909, 913, 991, 1028, 1054, 1058, 1066, 1173.

*References 42, 89, 200, 243, 254, 263, 283, 343, 357, 374, 384, 387, 419, 467, 501, 560, 570, 586, 623, 625, 638, 662, 682, 727, 756, 802, 841, 914, 921, 935, 972, 981, 1040, 1055, 1071, 1162.

FIG. 166.15 Erythematous, discrete, maculopapular, and petechial rash of echovirus 9 infection. (From Cherry JD. Newer viral exanthems. *Adv Pediatr.* 1969;16:233–86.)

major manifestations of echovirus 9 infection. Exanthem occurs in approximately one-third of cases. The prevalence of exanthem is related inversely to age; 57% of children younger than 5 years of age have a rash, whereas only 6% of those older than 10 years have similar cutaneous findings.⁶⁸⁵ The rash usually is rubelliform, but in addition or as the sole manifestation, petechiae are common findings. Rash and fever generally appear at approximately the same time, and frequently the illness closely mimics meningococcemia. The rash usually lasts approximately 3 to 5 days. In one instance, the rash progressed to a vesicular stage.⁶⁸² Drago and associates³⁰⁷ noted a 24-year-old woman with echovirus 9 infection with herpangina and a maculopapular rash with petechiae that was localized to her buttocks.

Echovirus 11

Exanthem occasionally occurs with echovirus 11 infection, and it varies considerably in appearance.^{42,127,200,210,294,1011} The most notable lesions have been bug bite–like vesicles and urticaria.²¹⁰ A child with subacute recurrent vesicular lesions²¹⁰ and a woman with a disseminated vesicular eruption were reported.²⁹⁴

Echovirus 13

One child with a maculopapular eruption was described.⁴⁹⁷ During an outbreak of echovirus 13 aseptic meningitis in Israel, 15 patients had a concomitant exanthem.¹⁰⁴¹

Echovirus 14

Echovirus 14 is a rare cause of exanthem, and few details are available.^{42,981} One child with a scarlatiniform eruption and aseptic meningitis was reported.⁹⁸¹

Echovirus 16

The first of the enteroviral exanthematous diseases to be described was that caused by echovirus 16. It initially was studied by Neva and Enders⁸³¹ and, later, by Neva and colleagues,⁸³² and the illness was called *Boston exanthem*. Two outbreaks of echovirus 16 infection with exanthem were documented by Neva⁸³⁰ in 1951 and by Neva and Zuffante⁸³³ in 1954, and another occurred in Paris in 1960.²⁵⁷ Since then, Boston exanthem has been reported only once. Seven cases were observed in 1974.⁴⁵⁰

The exanthem associated with echovirus 16 infection is erythematous, maculopapular, and discrete and is similar to that of other enteroviral infections. What has been unique with echovirus 16 infection is the relationship of rash with fever. Frequently, the illness resembles roseola in that the rash occurs at the time of or after defervescence.^{197,450} Ulcerative lesions on the soft palate and tonsillar pillars (herpangina) sometimes have been observed.

Echovirus 17

Rash is an occasional occurrence in echovirus 17 infection.^{42,124,204,212} In one outbreak, transient erythematous rashes were noted.¹²⁴ In cases

that one of us (J.D.C.) studied, papular, maculopapular, and papulo-vesicular lesions were noted; two patients had herpangitic enanths, and one had aseptic meningitis.^{204,212}

Echovirus 18

Kennett and associates⁶¹⁰ described an extensive epidemic of echovirus 18 infection in which aseptic meningitis with or without exanthem was the major finding. In 15 patients, exanthem was the chief complaint. The rash was described as rubelliform. Most patients were children, but adults also had exanthem.

Echovirus 19

In one extensive epidemic of echovirus 19 infection, exanthem was a common occurrence.²⁵² Fifty percent of children younger than 6 months of age had exanthem, and many of these infants presented a picture of septicemia with peripheral circulatory failure. Rash occurred in adults and older children, but the percentage decreased with age. The rash usually was erythematous, maculopapular, and discrete. It started on the face and upper part of the trunk and spread to the extremities. Fever occurred in all cases, and meningitis and signs of upper respiratory tract involvement were noted frequently. In another outbreak of echovirus 19 infection, 33% of those infected had exanthem,⁴¹⁷ whereas in an outbreak studied by Cramblett and colleagues,²⁶¹ exanthem was a rare finding.

Echovirus 21

A 19-day-old infant with aseptic meningitis and rash was reported.²³¹

Echovirus 24

A 4-month-old infant had rash and aseptic meningitis as a result of echovirus 24 infection.²³¹

Echovirus 25

Echovirus 25 has been associated with an array of different skin manifestations.^{80,205,443,806,825} In one epidemic of febrile pharyngitis, approximately one third of the patients had exanthem.⁸⁰⁶ The rash usually was maculopapular and discrete, but occasionally it displayed a morbilliform confluence. The rash most frequently occurred during the period of defervescence.

Of considerable interest are two children with acute hemangioma-like lesions.²⁰⁵ The lesions were erythematous and papular and surrounded by a 1- to 4-mm-wide halo of blanched-appearing skin. The center of each lesion had a bright red dot that suggested a dilated capillary or terminal arteriole. The whole lesion blanched with pinpoint pressure applied to its middle.

Echovirus 30

Echovirus 30 is a common cause of epidemic aseptic meningitis, and exanthem occasionally is noted concomitantly. The rash is macular or maculopapular.^{42,200,542,593,680,1092,1192}

Echovirus 32

Two children with echovirus 32 infection and hemangioma-like lesions were described by Cherry and colleagues.²⁰² Some lesions seemed to be composed of many dilated capillaries; they easily blanched with pressure.

Echovirus 33

Four patients with aseptic meningitis and echovirus 33 infection also had exanthem.^{595,607} Two adults had vesicular lesions that suggested HSV infection.²⁸⁶

Enterovirus 71

Kennett and associates⁶⁰⁹ in Australia studied 49 patients with EV 71 infection and noted exanthem in 11. Six patients had aseptic meningitis, and rash was the predominant complaint in 5 patients. The exanthems varied: some were erythematous maculopapular, some vesicular, and some a combination of lesions. Two children had hand-foot-and-mouth disease, and a single child had a florid, diffuse erythematous rash. Since the 1970s, outbreaks and epidemics of hand-foot-and-mouth disease

caused by EV 71 have been noted throughout the world.* Most notable have been epidemics in Asian-Pacific countries. In addition to hand-foot-and-mouth disease, these illnesses also have severe encephalitic manifestations.

Parechoviruses

Exanthem has been noted in association with PeV infections on several occasions. In some reports, genotypes have been reported,^{93,551,879,1018,1116} whereas in others only PeV is indicated.^{59,907,1124,1125,1179} In one study that included 110 PeV infections, 9.1% had unspecified exanthems, and, in addition, 6.4% had hand-foot-and-mouth disease.⁵⁵¹ Genotypes included types 1 and 3. In a study by Selvarangan and associates¹⁰¹⁸ of CNS infections with PeV type 3, 60.3% had associated maculopapular exanthems. A morbilliform rash has been described in three infants with genotype 1 infections.⁹³ Genotypes 1 to 6 have all had infections associated with rash.

Clinical Exanthematous Manifestations and Syndromes

The major clinical exanthematous manifestations and syndromes of coxsackieviruses and echoviruses are presented in Table 166.17. Unusual findings include hemangioma-like lesions with echoviruses 25 and 32, anaphylactoid purpura with coxsackievirus A4 and echoviruses 9 and 18, zoster-like rash with echoviruses 5 and 6, pityriasis-like rash with echovirus 6, and chronic or recurrent rash with coxsackievirus A16 and echovirus 11.

Neurologic Manifestations

Neurologic illness is a frequent manifestation of infection with most EVs and PeV. The most common illness is aseptic meningitis, but encephalitis and other manifestations also occur. Parechoviral neurologic manifestations are particularly common and significant in neonates and during the first 3 months of life (these are discussed in the later section on neonatal infections). The prevalence of nonpolio EVs and PeVs in the various clinical syndromes is presented in Table 166.18.

Aseptic Meningitis

Aseptic meningitis caused by EVs occurs both in epidemics and as isolated cases. The etiologic agents most often associated with epidemic disease are presented in Table 166.19. Epidemic disease has occurred most commonly with coxsackievirus B5, echoviruses 4, 6, 9, 13, and 30 and EV 71. In general, illness occurs more frequently in children, but if a specific outbreak is large, adults also are involved. Virtually all patients have fever and pharyngitis; other respiratory manifestations occur commonly. Rash is a frequent occurrence but varies with the specific viral agents. Between one-third and one-half of all patients with echovirus 9 meningitis have exanthem. Abdominal pain is a common symptom in patients with epidemic enteroviral aseptic meningitis.

Except for rash, herpangina, pleurodynia, or myocarditis, little else occurs clinically to help identify the origin in a sporadic case of aseptic meningitis. Initial symptoms include fever, headache, malaise, nausea, and vomiting. The headache usually is frontal or generalized; adolescents and adults frequently note retrobulbar pain. Pain in the neck, back, and legs occurs commonly. Abdominal pain is noted in approximately one-fifth of patients, but this symptom varies with the specific etiologic viral type. Photophobia is a common occurrence.

Physical examination reveals a temperature in the range of 38° to 40°C (100.4°–104°F). Skin rash occurs often and usually is erythematous, maculopapular, and discrete. Frequently, particularly with echovirus 9 infection, the rash is petechial and suggests meningococcemia. Hand-foot-and-mouth disease is a common event in cases of aseptic meningitis caused by EV 71 infection.^{176,183,491,646,759} Pharyngitis occurs frequently. Generalized muscle stiffness or spasm usually is observed, although the degree varies considerably; the Kernig and Brudzinski signs are positive in fewer than half of the cases. Deep tendon reflexes usually are normal. In one study, 9% of children with enteroviral meningitis had the

syndrome of inappropriate secretion of antidiuretic hormone.¹⁹² The onset of this syndrome was noted 36 hours after admission to the hospital, and it usually lasted less than 2 days.

Examination of CSF reveals considerable variation among patients and in the same patient on repeated examination. CSF leukocyte counts vary from a few cells to a few thousand per cubic millimeter; the median is in the range of 100 to 500 cells/mm³. The percentage of neutrophils also varies greatly. Initial examinations frequently reveal a predominance of neutrophils, but rarely more than 90%, as seen in bacterial disease. Usually, a range between 30% and 60% neutrophils is found on initial examination. Repeated examinations of CSF demonstrate an increasing percentage of mononuclear cells. Dagan and colleagues²⁷³ observed that the rate of isolation of virus from the CSF in enteroviral meningitis was directly proportional to the number of leukocytes in the fluid. Dalal and associates²⁷⁸ found that children with echovirus 4 meningitis had elevated values of interleukin-6 and interferon in the CSF and that the interleukin-6 value correlated with the CSF leukocyte values.

CSF protein levels usually are elevated mildly, and glucose concentrations usually are normal; hypoglycorrhachia rarely occurs.^{46,214,327,665,684,736,1020,1029,1033,1060} Occasionally, the CSF findings suggest tuberculosis meningitis with mononuclear pleocytosis, hypoglycorrhachia, and elevated protein levels.⁷³² A child with coxsackievirus B4 meningitis had eosinophils in the CSF.²¹³ The results of other routine laboratory studies such as the WBC count occasionally are abnormal but are not helpful diagnostically.

The duration of illness varies significantly. In most patients, the temperature returns to normal within 4 to 6 days, and disability as a result of neurologic involvement lasts 1 to 2 weeks. Occasionally, the pattern of illness is biphasic; an initial period with fever, headache, nausea, vomiting, and muscle aches and pains of a few days' duration is followed by general recovery and then a return to the same symptoms in addition to more pronounced neurologic involvement.

Wilfert and associates¹¹⁶⁶ performed a longitudinal assessment of children who had enteroviral meningitis early in life and found that receptive language functioning was significantly worse than that of children in a control group without meningitis. In another study, Sells and colleagues¹⁰¹⁷ examined the long-term effects of CNS enteroviral infection in 19 children. Of this group, 11 were free of detectable abnormalities, 5 had possible defects, and 3 had definite neurologic sequelae. In more recent studies, patients who have had meningitis have performed as well as control subjects in follow-up developmental evaluations.^{90,961,966}

Encephalitis

In the United States, approximately 2500 cases of encephalitis per year, on average, are reported to the CDC.¹⁵⁴ In this group, only approximately 2% of these patients demonstrate an enteroviral origin of illness. However, the seasonal pattern of disease and the absence of arboviral activity in many geographic locations suggest that 500 to 1000 cases of enteroviral encephalitis actually occur each year in the United States. The prevalence of coxsackieviruses, echoviruses, EVs, PeVs, and SAFVs as etiologic agents in encephalitis is presented in Table 166.18. Echovirus 9 is the most frequent cause of enteroviral encephalitis. Other enteroviral types commonly associated are echoviruses 4, 6, 11, and 30 and coxsackievirus B5. Echoviruses 4, 6, and 11 have been noted most frequently over a long period.

In general, the prognosis in encephalitis caused by enteroviral infection is good, but fatalities do occur. The viral types that have been isolated from the brain or CSF in fatal cases are as follows: coxsackieviruses B3 and B6; echoviruses 2, 9, 17, and 25; and EV 71.^{440,623} First noted in Japan in the 1970s were outbreaks of hand-foot-and-mouth disease associated with a diverse array of encephalitic manifestations.⁸⁷² Since the mid-1970s, epidemics of hand-foot-and-mouth disease with encephalitis mainly caused by EV 71 have been occurring in Asian-Pacific countries.*

In an outbreak in Taiwan in 1998, 30 of 78 (38%) patients with severe illness had encephalitis, and 25 of these patients with encephalitis also had pulmonary edema or hemorrhage, two had myocarditis, and one had acute flaccid paralysis.⁴⁹¹ In another study, 30 of 34 children with CNS involvement had brainstem encephalitis, and 9 of this group (30%) died.¹¹⁴¹ Children who recovered from EV 71 encephalitis associated with cardiopulmonary failure often had neurologic sequelae with delayed neurodevelopment, reduced cognitive function, and attention-deficit/hyperactivity-related problems.^{181,389,917,1103}

Paralysis

Paralysis caused by anterior horn cell disease occasionally results from infection with nonpolio EVs. In contrast to the prevalence of poliovirus,

which in the prevaccine era resulted in epidemic paralytic disease, paralysis caused by nonpolio EVs usually is a sporadic event. Coxsackievirus A7 has been associated with outbreaks of paralytic disease on three occasions.^{437,439,1133} Many cases of illness similar to poliomyelitis have occurred during outbreaks and epidemics of illness caused by EV 71 and by EV D68.* A 6-year-old girl developed acute flaccid paralysis in association with EV C105 infection.⁵⁰⁰ Paralytic disease also has been noted during epidemics of acute hemorrhagic conjunctivitis caused by EV 70.^{1135,1198}

Guillain-Barré Syndrome and Transverse Myelitis

As Table 166.18 shows, many coxsackieviruses and echoviruses apparently have been associated with Guillain-Barré syndrome. In general, no specific viral types appear to cause the disease. Rather, the disease occurs sporadically in association with the prevalent enteroviral types. However, in South Wales, United Kingdom, a cluster of atypical Guillain-Barré syndrome cases in adults was temporally associated with EV D68.¹¹⁷⁰ Two children also had Guillain-Barré syndrome.

Other Neurologic Illnesses

Cerebellar ataxia has been associated with coxsackieviruses A4, A7, A9, B3, and B4 and echoviruses 6, 9, and 16 (see Table 166.18). A 16-month-old boy with ataxia was found to have SAFV in the CSF and in a fecal sample.⁸³⁶ Scott¹⁰¹¹ specifically commented on peripheral neuritis with echovirus 9 infection. Coxsackievirus A9 has been associated with focal encephalitis and acute hemiplegia on two occasions,^{170,200} and echovirus 25 infection was noted in a 5-year-old boy with focal encephalitis and subacute hemichorea.⁸⁹⁷ Coxsackievirus B4 was isolated from the CSF of a 22-year-old woman with intracranial hypertension,¹¹⁸⁵ and postencephalitis Parkinson syndrome occurring after an episode of coxsackievirus B2 meningoencephalitis was described.¹¹³⁷ Coxsackievirus B3 and EV 71 infections have been associated with opsoclonus-myoclonus.⁶⁵⁴ The case of a 4-year-old boy with “Alice in Wonderland” syndrome (complex

symptoms of perceptual distortion) associated with coxsackievirus B1 infection was described.¹¹⁴⁰ A 16-month-old-boy had monosymptomatic ataxia in association with SAFV infection.⁸³⁶ The virus was recovered from the CSF.

Phillips and colleagues⁹⁰⁶ and Barrett and associates⁶³ noted the simultaneous occurrence of enteroviral and St. Louis encephalitis viral infection in the same community. In six instances, dual infections occurred, and the afflicted children tended to have more serious illnesses. Ribai and colleagues⁹⁴⁸ noted an 18-month-old boy with transient cerebral arteriopathy and an enteroviral infection. The child had aphasia, right hemiplegia, and seizures, which occurred intermittently over a 3-day period.

Ergul and associates³³⁴ described a 7-year-old boy with vestibular neuritis from whom enteroviral RNA was found in both the CSF and a nasopharyngeal sample. Multiple attacks of enteroviral aseptic meningitis in the same individuals have been noted occasionally.^{639,823}

Woodall and associates¹¹⁸³ found conserved enteroviral sequences in spinal cords from subjects with sporadic motor neuron disease and from one patient with possible familial motor neuron disease. Berger and associates⁸⁸ noted EV RNA sequences in spinal cord specimens from 13 of 17 patients with amyotrophic lateral sclerosis, but Walker and colleagues¹¹³⁶ could not duplicate these findings in a study of 20 spinal cord specimens from similar patients. Simonsen and coworkers¹⁰³¹

TABLE 166.19 Coxsackieviruses and Echoviruses Associated With Epidemic Aseptic Meningitis

Virus Type		Age Group	Common Non-neurologic Findings	References
Coxsackievirus	A7	Children and adults	Fever	434

noted an outbreak of vertigo in Wyoming in August of 1992 in which IgM antibody studies suggested an enteroviral origin.

Chronic Fatigue Syndrome and Fibromyalgia

From molecular techniques and antibody prevalence data, chronic enteroviral infections have been suggested to play a role in the chronic fatigue and postviral fatigue syndromes.^{32,137,247,810,1203} However, these findings have not been confirmed by other investigators.^{765,782,1064} More recently, Douche-Aourik and associates³⁰⁴ found enteroviral RNA in muscle biopsies from 4 of 30 (13%) patients with fibromyalgia or chronic fatigue syndrome but in no biopsy samples from 29 healthy subjects. However, in none of the four positive samples could the presence of VP1 enteroviral capsid protein be demonstrated using a specific monoclonal antibody. In another study, Lane and colleagues⁶⁷¹ found enteroviral RNA in muscle biopsy samples of 10 of 48 patients (20.8%) with chronic fatigue syndrome and in no samples from 29 control subjects. These investigators also found that nine of the 10 subjects with positive muscle biopsy results had abnormal lactate responses to exercise in the subanaerobic threshold exercise test. In an editorial relating to these data, Dalakas²⁷⁵ warned that similar findings in the past were “epiphenomenal” because EVs are ubiquitous in humans, and technical flaws inherently connected to contamination in laboratories working with these viruses are inevitable.

The greatest proponents for a causal role of EV in chronic fatigue syndrome have been Chia and Chia.^{217,219} Although these investigators have had extensive experience with chronic fatigue syndrome and have conducted several studies, none of their data had been adequately controlled.⁶⁴³ They have presented data suggesting that some cases of chronic fatigue syndrome are the result of chronic enteroviral infections of the stomach.^{221,220}

Sudden Infant Death

Balduzzi and Greendyke⁵⁶ recovered coxsackievirus A5 from the stool of a 1-month-old child who died suddenly. In a similar investigation

of sudden infant death, Gold and associates⁴¹⁶ recovered coxsackievirus A4 from the brains of three babies. Coxsackievirus A8 also was recovered from the stool of a child in whom anorexia was noted on the day before death. Coxsackievirus B3 was recovered at the autopsy of an infant who died suddenly on the eighth day of life.⁵⁶ In Hong Kong in 2012 two children with sudden deaths and recombinant coxsackievirus A2 viral infections were reported.¹¹⁹⁹ Neither child had myocarditis or encephalitis, but one had evidence of viral pneumonia. The viruses were recombinants involving coxsackievirus A2, A4, and EV 71. Morens and colleagues⁸⁰² noted sudden infant death eight times in association with enteroviral infection; PeV was found on two occasions. In a subgroup of infants with sudden unexplained death in whom the “clinical, biologic, and histologic” findings suggested viral infection, evidence of enteroviral infection was found more frequently than in infants without findings of viral infection.⁴²⁵ Specifically, enteroviral RNA was detected in the respiratory tract in 54% of the viral infection group and in none of the group without findings suggestive of viral infection. These results were supported by IgM antibodies to group B coxsackieviruses in 56% of the first group and in none of the second group. Four infants with suspected sudden infant death syndrome were found to have coxsackievirus B3 myocarditis with minimal histopathologic changes.²⁹⁶ In five instances of crib death in one study, echovirus 11 was isolated from the lungs in two cases, from the myocardium in one case, and from the nose or feces in the other two cases.⁹⁷ Drexler and associates³¹⁰ noted RNA evidence of genotype 2 SAFV in the CSF of an infant with sudden infant death syndrome.

Chronic Enteroviral Infections in Immunocompromised Patients

Patients with cell-mediated and combined immunodeficiencies are susceptible to chronic and often fatal infections with many viruses.³⁷⁹ Patients with agammaglobulinemia and normal cell-mediated function generally survive infections with these same viruses. EVs are the exception, however, in that chronic, unusual infections with a variety of EVs have

been reported.* The most common illness is meningoencephalitis, but arthritis and polymyositis are other frequent findings. Echovirus 11 has been the most common cause of chronic infection, but the following other EVs also have been causative: echoviruses 2, 3, 5, 6, 7, 9, 13, 14, 15, 17, 18, 19, 21, 24, 25, 26, 29, 30, and 33; coxsackieviruses A11, A15, B1, B2, and B3; and PeV 1.⁷⁵¹ EVs have been recovered from many other body sites, such as the liver, heart, lung, pancreas, lymph nodes, bone marrow, muscle, throat, and stool, in addition to the CSF.

Several patients with X-linked agammaglobulinemia have had polymyositis-like or dermatomyositis-like syndromes caused by echovirus infections; the following echoviruses have been implicated: types 2, 3, 5, 9, 11, 17, 19, 24, 25, 30, and 33.^{62,264,762} The case of a 15-year-old boy with X-linked agammaglobulinemia and chronic arthritis caused by echovirus 11 was reported.¹² Three children with X-linked hyper-IgM syndrome and persistent enteroviral meningoencephalitis were described.²⁶⁹ Persistent enteroviral infections of the CNS were reported in pediatric and adult patients infected with HIV.^{320,882} In addition, enteroviral infections caused deaths in bone marrow transplant recipients.^{31,380}

Congenital Infections

Abortion

Landsman and associates⁶⁶⁸ studied 2631 pregnancies during an epidemic of echovirus 9 and could find no difference in antibody to echovirus 9 in women who aborted and in those who delivered term infants. A similar study in Finland revealed no increase in the abortion rate in women infected in early pregnancy with echovirus 9.⁹³⁵ Although coxsackieviral infections occur commonly, epidemics with specific viral types involving large populations have not been studied.

Two women with coxsackievirus A16 hand-foot-and-mouth disease had spontaneous abortions.⁸⁶⁸ In one instance, coxsackievirus A16 was recovered from the products of conception. Frisk and Diderholm³⁷⁰ found that 33% of women with abortions had IgM antibody to coxsackieviruses B, whereas only 8% of control subjects had similar antibody. In a second, larger study, the same research group confirmed their original findings.⁴⁷

Ljungan virus (a PeV) is endemic in some rodent populations, and it can cause fetal death in these animals. Krous and Langlois⁶⁵³ and Samsioe and colleagues⁹⁸⁷ suggest that this virus may be the cause of some intrauterine deaths in humans. In one study, both PCR and immunohistochemical staining identified Ljungan virus in specimens from five human intrauterine fetal deaths.⁹⁸⁷

Congenital Malformations

In a large prospective study, Brown and Karunas¹²¹ made a serologic search for selected maternal enteroviral infections in association with congenital malformations. Sera from 630 mothers of infants with anomalies and from 1164 mothers of children without defects were studied carefully. Specifically, serologic evidence of infection with coxsackieviruses B1, B2, B3, B4, B5, and A9 and with echoviruses 6 and 9 was sought during the first trimester and during the last 6 months of pregnancy. In this study, infants were examined for 113 specific abnormalities; these anomalies were grouped into 12 categories for analysis. The investigators demonstrated a positive correlation between maternal infection and infant anomaly with coxsackieviruses B2, B3, B4, and A9. The overall anomaly rate associated with first trimester infection with coxsackievirus B4 was significantly higher than that in control subjects. Maternal coxsackievirus B2 infection throughout pregnancy, coxsackievirus B4 infection during the first trimester of pregnancy, and infection with at least one of the five group B coxsackieviruses during pregnancy were associated with urogenital anomalies in contrast to control subjects. Coxsackievirus A9 infection was associated with digestive anomalies and coxsackieviruses B3 and B4 with cardiovascular defects. When group B coxsackieviruses were analyzed as a group (B1–B5), an overall association with congenital heart disease was found; the likelihood of having cardiovascular anomalies was increased when maternal infection with two or more group B coxsackieviruses occurred.

Gauntt and colleagues³⁹³ found that ventricular fluid from four of 28 babies with severe anatomic defects contained neutralizing antibody to one or more coxsackievirus B types. In one case, specific IgM antibody to coxsackievirus B6 was demonstrated.

In a serologic study in Scotland, Ross and colleagues⁹⁶² found no association between maternal coxsackievirus B infection and fetal developmental anomalies. Elizan and associates³³⁰ were unable to find any relationship between maternal infection with group B coxsackieviruses and congenital CNS malformations. In three studies, no association between maternal echovirus 9 infection and congenital malformation was noted.^{638,668,935}

Niklasson and associates⁸⁴² studied CNS malformations in terminated pregnancies. PeV (Ljungan virus) was diagnosed in nine of 10 cases of hydrocephalus and in five of nine cases of anencephaly, whereas this virus was found in only one of 18 trisomy 21 control subjects.

Prematurity and Stillbirth

Bates⁶⁸ reported an 8-month-old stillborn fetus with calcific pancarditis and hydrops fetalis at autopsy. Fluorescent antibody study revealed coxsackievirus B3 antigen in the myocardium. Burch and colleagues¹²⁹ reported three stillborn infants who had fluorescent antibody evidence of coxsackievirus B myocarditis, one each with coxsackieviruses B2, B3, and B4. These investigators also described a premature boy who had histologic and immunofluorescent evidence of cardiac infection with coxsackieviruses B2, B3, and B4; he lived only 24 hours.

Freedman³⁶⁸ reported the occurrence of a full-term stillbirth in a woman infected with echovirus 11. Because the baby had no pathologic or virologic evidence of infection, Freedman attributed the event to a secondary consequence of maternal infection caused by fever and dehydration rather than primary transplacental infection. In another stillbirth in which echovirus 11 was recovered from amniotic fluid, the fetus was found to have evidence of focal encephalitis, massive adrenal hemorrhage, and diffuse subarachnoid hemorrhage.¹⁰³⁶ Echovirus 27 was recovered from amniotic fluid in an intrauterine fetal death at 28 weeks of gestation.⁸³⁴ A 26-week, 1300-g stillborn fetus with hydrocephalus, fibrotic peritonitis, and hepatosplenomegaly was found by PCR and immunohistochemical study to have an EV 71 infection.²³⁵ A baby of 26 weeks' gestation with nonimmune hydrops fetalis and an intrauterine infection with coxsackievirus B3 was reported by Ouellet and coworkers.⁸⁷⁸

NEONATAL INFECTIONS

Epidemiology and Pathogenesis

Neonatal infection with EVs and PeVs can result from transplacental viral transmission, contact infection during birth, and human-to-human contact after birth. Transplacental passage of coxsackieviruses and echoviruses at term has been noted on many occasions. Benirschke¹²²⁰ studied the placentas in three cases of congenital coxsackievirus B disease and could find no histologic evidence of infection. In 1956, Kibrick and Benirschke¹²²¹ reported the first case of intrauterine infection with coxsackievirus B3. In this instance, the infant was delivered by cesarean section and became symptomatic several hours after birth. Brightman and associates¹¹⁸ recovered coxsackievirus B5 from the placenta and rectum of a premature infant. No histologic abnormalities of the placenta were noted.

Berkovich and Smithwick⁹⁴ noted an asymptomatic neonate who had specific IgM PeV 1 antibody in cord blood, thus suggesting intrauterine infection with this virus. Hughes and colleagues⁵²⁵ reported a newborn infant with echovirus 14 infection who had markedly elevated IgM (190 mg/dL) on the sixth day of life. This child probably also was infected in utero. In addition, echovirus 19 has been noted in a transplacentally acquired infection.⁹⁰³ Other evidence of intrauterine infection has been presented for coxsackieviruses A4, B1, B2, B3, B4, and B5 and echoviruses 9, 11, and 19.^{68,82,107,200,212,338,458,579,594,731,878,903,1084}

Little definitive evidence exists for either ascending infection or contact infection with coxsackieviruses or echoviruses during birth. However, transmission of infection during the birth process seems probable.^{196,212,594} The fecal carriage rate of EVs in asymptomatic adult patients varies between 0% and 6% or higher in different population

*References 12, 97, 103, 255, 264, 269, 316, 319, 335, 448, 452, 480, 599, 751, 968, 1120, 1151, 1153, 1165.

groups.²⁰⁰ Cherry and colleagues²¹² reported that in 2 of 55 mothers (4%), EVs were present in feces shortly after delivery.

Coxsackievirus B5 was recovered from the cervixes of four women with febrile illnesses during the third trimester of pregnancy.⁹⁴⁴ Echovirus 11 was isolated from the cervix of a mother whose baby became ill on the third day of life with fatal echovirus 11 necrotizing hepatitis.⁹⁴³ Chang and colleagues¹⁸⁵ detected coxsackievirus B3 in breast milk of two symptomatic mothers, and their babies both suffered severe illnesses with hepatic necrosis and meningitis caused by coxsackievirus B3.

Several epidemics with coxsackieviruses and echoviruses in newborn nurseries have been studied.^{118,143,777,818} Brightman and associates¹¹⁸ observed an epidemic of coxsackievirus B5 in a premature nursery. Their data suggested that the virus was introduced into this nursery by an asymptomatic infant who had been infected in utero. Secondary infections occurred in 12 babies and two nurses. The timing of the secondary cases suggested that three generations had occurred and that the nurses had been infected during the second generation. The investigators suggested that the infection had spread from infant to infant and from infant to nurse.

Javett and associates⁵⁶³ reported an acute epidemic of myocarditis associated with coxsackievirus B3 infection in a Johannesburg, South Africa maternity home. Unfortunately, no epidemiologic investigation or search for asymptomatic infected infants was performed. However, in analyzing the dates of onset of the illnesses, single infections apparently occurred for five generations, and then five children became ill within a 3-day period.

Kipps and colleagues⁶³³ carried out epidemiologic investigations in two coxsackievirus B3 nursery epidemics. In the first epidemic, the initial infection probably was transmitted from a mother to her baby; this baby then was the source of five secondary cases in newborn infants and one illness in a nurse. Four of the five secondary cases were located on one side of the nursery, but only one crib was close to that of the index baby, and this crib did not adjoin the cribs of the three other contact cases. In the second outbreak, a baby who also was infected by his mother probably introduced the virus into the nursery. The three secondary cases were geographically far removed from the primary case.

Cramblett and colleagues²⁵⁹ reported an outbreak of echovirus 11 disease in four infants in an intensive care nursery. All infants were in enclosed incubators, and three patients became ill within 24 hours; the fourth child became ill 4 days later. Echovirus 11 was recovered from two members of the nursery staff. These data suggest that transmission from personnel to infants occurred because of inadequate washing of hands.

In another outbreak in an intensive care unit, the initial patient was transferred to the nursery because of severe echovirus 11 disease.⁸¹⁸ After transfer, the senior house officer and a psychologist in the unit were infected. The investigators inferred that these infected personnel spread the disease by respiratory droplet to nine other babies. In another nursery outbreak of echovirus 11, Mertens and colleagues⁷⁷⁷ found that the infection spread through close contact between infected newborns and the nurses in the unit. Spread of infection was interrupted with the installation of vigorous hygienic and isolation measures. In an outbreak of echovirus 11 in an intermediate care unit, Kinney and colleagues⁶³² found that gavage feeding, mouth care, and being a twin were risk factors for acquiring illness.

Many other instances of isolated nursery infections and small outbreaks with coxsackieviruses and echoviruses have been reported. The most consistent source of original nursery infection seems to be transmission from a mother to her baby,^{*} but virus can be introduced into the nursery by hospital personnel.^{543,673,1066}

In a longitudinal study of neonatal enteroviral infections carried out during the summer and fall of 1981, Jenista and associates⁵⁶⁵ found that the nonpolio enteroviral infection rate was 12.8%. Lower socioeconomic status and lack of breastfeeding were found to be risk factors for acquiring infection. Nonpolio enteroviral infections were determined to be a significant cause for readmission of the cohort neonates to the hospital.

During a community outbreak of echovirus 11 disease, Modlin⁷⁹⁰ found that passive transplacental passage of antibody to neonates prevented the development of severe disease but not mucosal infection.

Clinical Manifestations

Enteroviral and parechoviral infections in neonates result in a wide variety of clinical manifestations ranging from asymptomatic infection to fatal encephalitis and myocarditis.²⁰⁰ An overview by illness category and prevalence is presented in Table 166.20.

Inapparent Infection

Although inapparent infection probably occurs occasionally with many different EVs, little documentation of this assumption exists. Cherry and colleagues²¹² studied 590 normal neonates during a 6-month period and noted only a single asymptomatic infection. This child was infected in utero or immediately thereafter with coxsackievirus B2. The mother had an upper respiratory tract illness 10 days before delivery.

During a survey of perinatal viral infections, 44 babies were found to be infected with PeV 1 in the study period May to December of 1966 (I. Jack, et al, personal communication, 1967). The prevalence of virus and the incidence of new infections during this period were fairly uniform. No illness was attributed to PeV 1 infection, and the virus disappeared from the nursery in mid-December. Asymptomatic infections with PeV 1 were noted on two other occasions.^{93,824} Infections without evidence of illness also have been noted with coxsackieviruses A9, B1, B4, and B5 and echoviruses 3, 5, 9, 11, 13, 14, 20, 30, and 31.^{200,325,342,402,543,554,565,673,808,1066}

Mild, Nonspecific Febrile Illness

In a review of 338 enteroviral infections in early infancy, 9% were classified as nonspecific febrile illnesses.⁸⁰¹ Illness may be sporadic or part of an outbreak with a specific viral type. When the illness is part of an outbreak, the clinical manifestations vary, depending on the viral type; some infants have aseptic meningitis and other signs and symptoms, whereas others simply have nonspecific fever. Specific viruses related to nonspecific fever are listed in Table 166.20. Although by definition illness in this category is mild, awareness that viral infection may be extensive is important. When sought, virus may be isolated from the blood, urine, and CSF of infants with mild illnesses.^{65,557} In an outbreak of relatively benign illness caused by echovirus 7 in six neonates, all the infants were found to have high C-reactive protein values.²⁷²

Sepsis-Like Illness

The main diagnostic problem in neonatal enteroviral and parechoviral infections is differentiation of bacterial from viral disease. Even in an infant with mild, nonspecific fever, bacterial disease must be considered strongly. The sepsis-like illness described here always is alarming. Illness is characterized by fever, poor feeding, abdominal distention, irritability, rash, lethargy, and hypotonia.^{59,450,463,665,907,1018,1125,1179} Other findings include diarrhea, vomiting, seizures, and apnea. In severe, frequently fatal illnesses, most often caused by echovirus 11 infection, jaundice, hepatitis, disseminated intravascular coagulation (DIC), thrombocytopenia, and hypotension occur.^{579,789,809,943}

Sepsis-like illness is a common occurrence. Morens⁸⁰¹ noted its presence in one-fifth of 338 enteroviral infections in infants. In an attempt to differentiate bacterial from viral disease, Lake and associates⁶⁶⁵ studied 27 infants with enteroviral infection. WBC counts were not helpful because the total count, the number of neutrophils, and the number of band-form neutrophils were elevated in most cases. Of most importance were historical data. Most mothers had experienced a recent febrile, viral-like illness. In addition, other factors often associated with bacterial sepsis, such as prolonged rupture of membranes, prematurity, and low Apgar scores, were unusual findings in the enteroviral infection group. Bone marrow failure developed in a newborn baby boy with a sepsis-like illness caused by echovirus 11 infection.¹⁰⁷⁷ The neutropenia resolved spontaneously, and the thrombocytopenia normalized after treatment with IVIG.

Abzug⁶ reviewed the prognosis in 16 neonates who had a sepsis-like illness with hepatitis and coagulopathy. The case-fatality rate was 31%. In addition to having hepatitis and coagulopathy, the five patients with fatal cases had myocarditis and three patients had encephalitis. The

follow-up of six survivors noted normalization of liver function and platelet counts and the absence of subsequent significant medical problems.

Respiratory Illness

Respiratory complaints generally are overshadowed by other manifestations of neonatal enteroviral disease. Only 7% of 338 enteroviral infections in early infancy were classified as respiratory illness in one study.⁸⁰¹ Herpangina has been observed and photographed only once; Chawarewong and associates¹⁹⁰ noted several infants with herpangina and coxsackievirus A5 infection.

Hercik and colleagues⁴⁷⁷ reported an epidemic of respiratory illness in 22 neonates associated with echovirus 11 infection. All these infants

had rhinitis and pharyngitis, 50% had laryngitis, and 32% had interstitial pneumonitis. Berkovich and Pangan⁹³ studied respiratory illnesses in premature infants and reported 64 babies with illness, 18 of whom had virologic or serologic evidence of PeV 1 infection. In addition, many had high but constant levels of serum antibody to PeV 1. Some of the infants with high antibody levels probably also were infected with PeV 1. The children with proved PeV 1 infection could not be differentiated clinically from those without evidence of such infection. Ninety percent of the infants had coryza, and 39% had radiographic evidence of pneumonia.

Except for echoviruses 11 and PeV 1, respiratory illness associated with EVs has occurred sporadically. The following other viruses have been noted: coxsackieviruses A5, A9, B1, B4, and B5 and echoviruses

9, 17, 18, 19, 20, 22, and 31. In the review by Morens,⁸⁰¹ only seven of 338 enteroviral infections of infancy were classified as pneumonia. A newborn with an echovirus 11 infection developed meningitis, DIC, and persistent pulmonary hypertension.¹¹⁶⁸ Postmortem examination revealed pneumonia, hyaline membranes, pulmonary interstitial emphysema, meningitis, and DIC.

Eichenwald and Kotsevalov³²⁶ recovered echovirus 20 from four full-term infants younger than 8 days of age. Although these infants were asymptomatic, they were found to be colonized extensively with staphylococci, and they disseminated these organisms into the air around them. Because of this ability to disseminate staphylococci, they were called *cloud babies*. The investigators thought these cloud babies contributed to the epidemic spread of staphylococci in the nursery. Because active staphylococcal dissemination occurred only when echovirus 20 could be recovered from the nasopharynx, viral-bacterial synergistic activity was thought to be present.

Gastrointestinal Manifestations

Significant gastrointestinal illness occurs in approximately 7% of enteroviral infections of infancy.⁸⁰¹ Vomiting and diarrhea occur commonly but usually are only part of the overall illness complex and not the major manifestations. In 1958, Eichenwald and associates³²⁵ described epidemic diarrhea associated with echovirus 18 infection. In a nursery unit of premature infants, 12 of 21 babies were mildly ill. Neither temperature elevation nor hypothermia occurred. Six infants were lethargic and listless, and moderate abdominal distention developed in two infants. The diarrhea lasted from 1 to 5 days; these infants had five or six watery, greenish stools per day, occasionally expelled explosively. Two infants had a small amount of blood, but no mucus or pus cells, noted in their stools. Five babies in another nursery also had similar diarrheal illness. Echovirus 18 was recovered from all ill infants.

In 22 infants with epidemic respiratory disease caused by echovirus 11, all had vomiting as a manifestation of the illness.⁴⁷⁷ Linnemann and colleagues⁷⁰⁸ reported vomiting in 36% and diarrhea in 7% of neonates with echoviral infection. In another study, Lake and associates⁶⁶⁵ found diarrhea in 81% and vomiting in 33% of neonates with nonpolio enteroviral infections.

Hepatitis is an important neonatal nonpolio enteroviral illness. Morens⁸⁰¹ reported that 2% of neonates with clinically severe enteroviral disease had hepatitis. Lake and colleagues⁶⁶⁵ observed that hepatomegaly was present in 37% of neonates with enteroviral infection, and hepatosplenomegaly was observed by Hercik and associates⁴⁷⁷ in 12 of 22 newborns with echovirus 11 respiratory illness.

Severe hepatitis, frequently with hepatic necrosis, has been noted with echoviruses 6, 9, 11, 14, 19, 21, and 30.^{92,107,200,449,525,579,789,809,903,908} Echovirus 11 most often has been associated with severe and usually fatal hepatitis; findings include DIC and thrombocytopenia, as well as apnea, lethargy, poor feeding, and jaundice.

Philip and Larson⁹⁰³ reported three catastrophic neonatal echovirus 19 infections that resulted in hepatic necrosis and massive terminal hemorrhage. One infant, infected in utero, was symptomatic at birth. The Apgar score was 3, and multiple petechiae were observed. Generalized ecchymoses and apneic episodes occurred, and the infant died at 3.5 hours of age. Thrombocytopenia was noted, and echovirus 19 was isolated from the brain, liver, spleen, and lymph nodes. The other two infants who died of echovirus 19 infection were twins. They were normal during the first 3 days of life but then became mildly cyanotic and lethargic. Shortly thereafter, apneic episodes occurred, and jaundice and petechiae developed. Both twins became oliguric, and they died on the eighth and ninth days of life with severe, terminal gastrointestinal bleeding. Both twins were thrombocytopenic, and virus was recovered from systemic sites in both.

Pancreatitis was found in three of four newborns with coxsackievirus B5 meningitis⁶⁴² and in a coxsackievirus B4 infection at autopsy.¹¹⁷⁶ In other fatal coxsackievirus B infections, pancreatic involvement has been detected, but clinical manifestations rarely have been observed.

Lake and associates⁶⁶⁵ reported three infants with necrotizing enterocolitis. Coxsackievirus B3 was recovered from two of these infants, and coxsackievirus B2 was recovered from the third.

TABLE 166.21 Signs and Symptoms of Neonatal Coxsackievirus B Myocarditis

Category	Frequency (%)
Feeding difficulty	84

Modified from Kibrick S. Viral infections of the fetus and newborn. *Perspect Viral*. 1961;2:140–59.

Cardiovascular Manifestations

In contrast to enteroviral cardiac disease in children and adults, in which pericarditis is a common finding, neonatal disease almost always involves the heart muscle. Most cases of neonatal myocarditis are caused by coxsackievirus B infection, and nursery outbreaks have occurred on several occasions. In 1961, Kibrick⁶²² reviewed the clinical findings in 45 cases of neonatal myocarditis; his findings are summarized in [Table 166.21](#). Of interest is that many of the early experiences, particularly in South Africa, involved catastrophic nursery epidemics. Since the observation in 1972 of five newborns with echovirus 11 infection and myocarditis, no other nursery epidemics have been reported.³⁰⁹

The illness caused by group B coxsackieviruses most commonly was abrupt in onset, with symptoms of listlessness, anorexia, and fever. A biphasic pattern was noted in approximately one third of the patients. Progression was rapid, and signs of circulatory failure appeared in a 2-day period. If death did not occur, recovery occasionally was rapid but usually took place gradually over an extended period. Most patients had cardiac findings such as tachycardia, cardiomegaly, electrocardiographic changes, and transitory systolic murmurs. Many patients showed signs of respiratory distress and cyanosis. Approximately one third of the infants had signs suggesting neurologic involvement. Of the 45 cases analyzed by Kibrick,⁶²² only 12 patients survived.

In an echovirus 11 nursery outbreak reported by Drew,³⁰⁹ five of 10 babies had tachycardia out of proportion to their fever. Three of these babies had electrocardiograms; supraventricular tachycardia was noted in all, and ST-segment depression was observed in two patients' records. Supraventricular tachycardia also has occurred with coxsackievirus B infection.⁵⁵⁴ Echovirus 19 has been associated with myocarditis, and coxsackievirus A9 was noted in a child with pericarditis.^{261,1072}

In the 1970s, neonatal myocarditis caused by EVs was seen less commonly than it was in the 1950s and early 1960s. In his review, Morens⁸⁰¹ noted only two instances among 248 severe neonatal enteroviral illnesses. Hoi-shan Chan and Lun⁴⁹⁴ reported a neonate with coxsackievirus B4 myocarditis who developed a ventricular aneurysm.

Exanthem

Exanthem as a manifestation of neonatal enteroviral infection has been reported with coxsackieviruses B1, B3, and B5; with echoviruses 4, 5, 7, 9, 11, 16, 17, and 18; and with PeV 1, 3, 4, 5, and 6. In most instances, rash is just a minor manifestation of severe neonatal disease. In 27 infants studied by Lake and colleagues,⁶⁶⁵ 41% had exanthem. Cutaneous manifestations generally commence between the third and fifth days of illness. The rash usually is macular or maculopapular. Petechial lesions are noted occasionally. Surprisingly, vesicular lesions have not been described, nor has any rash illness in neonates been associated with coxsackievirus A16. Hall and associates⁴⁵⁰ reported two neonates with

echovirus 16 infections in which the illnesses resembled roseola. These patients had fever for 2 and 3 days, defervescence, and then the appearance of a maculopapular rash.

A newborn with a vesiculopapular-crusted rash on the face, trunk, and extremities caused by coxsackievirus B3 was reported by Theodoridou and associates.¹⁰⁸⁴ It was a congenital infection in which new lesions appeared over the course of a 5-day period, and the total duration of the rash was 10 days.

Neurologic Manifestations

As noted in Table 166.20, neurologic illness has been associated with coxsackieviruses B1, B2, B3, B4, and B5, many echoviruses and PeVs. In neonates, differentiating meningitis from meningoencephalitis usually is difficult. Meningoencephalitis occurs commonly in infants with sepsis-like illness, and postmortem studies revealed many infants with disseminated viral disease (heart, liver, adrenal glands) in addition to CNS involvement. In Morens' review,⁸⁰¹ 50% of the patients with enteroviral infection who were analyzed had encephalitis or meningitis.

The initial clinical findings in neonatal meningitis or meningoencephalitis are similar to those in nonspecific febrile illness or sepsis-like illness. Most often, the child is normal and then becomes febrile, anorectic, and lethargic. Jaundice frequently is noted in newborns, and vomiting occurs in neonates of all ages. Less common findings include apnea, tremulousness, and general increased tonicities. Seizures occur occasionally. Extensive white matter injury has been noted in neonatal PeV encephalitis.¹¹²⁴ This finding can be confused with white matter changes associated with hypoxic-ischemic injuries.

Examination of CSF reveals considerable variation in protein, glucose, and cellular values. In seven newborns with meningitis caused by coxsackievirus B5 studied by Swender and colleagues,¹⁰⁶⁶ the mean CSF protein value was 244 mg/dL, and the highest value was 480 mg/dL. The mean CSF glucose value was 57 mg/dL, and one of the seven infants had pronounced hypoglycorrhachia (a value of 12 mg/dL). The mean CSF leukocyte count in the seven babies was 1069 cells/mm³, with 67% polymorphonuclear cells. The highest cell count was 4526 cells/mm³, with 85% polymorphonuclear cells. In another study involving 28 children younger than 2 months of age in which coxsackievirus B5 was the implicated pathogen, 36% of the infants had CSF leukocyte counts of 500 cells/mm³ or greater.⁷³⁶ In this same study, only 13% of the infants had CSF protein values of 120 mg/dL or greater; 12% of the infants had glucose values lower than 40 mg/dL.

In summary, the CSF findings in neonatal nonpolio enteroviral and parechoviral infections frequently are similar to those in bacterial disease. In particular, the most consistent finding in bacterial disease, hypoglycorrhachia, is noted in approximately 10% of newborns with enteroviral meningitis.^{214,327,665,736,1066}

Johnson and associates⁵⁷⁰ reported a 1-month-old boy with right-sided facial paralysis and loss of abdominal reflexes. The facial paralysis persisted through convalescence; the reflexes returned to normal within 2 weeks. The boy was infected with coxsackievirus B2. Jones and associates⁵⁸¹ noted a neonate with coxsackievirus B1 meningoencephalitis and central diabetes insipidus.

Euscher and associates³³⁸ detected coxsackievirus RNA in placental tissue from six of seven newborn infants with respiratory difficulties and other manifestations at birth. Of these infants, one died shortly after birth, and the other six suffered neurodevelopmental delays.

CLINICAL MANIFESTATIONS: POLIOVIRUS

When a susceptible person has had effective contact with a poliovirus, one of several responses may occur, in the following order of frequency: (1) inapparent infection, (2) minor illness (abortive poliomyelitis), (3) nonparalytic poliomyelitis (aseptic meningitis), and (4) paralytic poliomyelitis.^{22,104,198,200,238,510} Paralytic poliomyelitis is the most dramatic expression of the infection and the only one clinically recognizable as caused by a poliovirus; it accounts for not more than 1% to 2% of infections during epidemics and considerably less under endemic conditions (see Fig. 166.5). The aseptic meningitis syndrome is similarly infrequent; nonspecific "minor illness" is estimated to occur in 4% to 8%, and 90% to 95% of those infected have inapparent infections.

Factors that determine the type of clinical response are poorly understood, but the degree of virulence of the virus and certain host characteristics are important.

Age has a significant effect on patterns of infection; older patients are more likely to have severe paralytic disease and a higher mortality rate. Pregnancy increases the risk, probably primarily because of hormonal factors but also because pregnant women may be exposed more to young children, who are the main sources of contagion. Tonsillectomy in the presence of inapparent infection can precipitate bulbar poliomyelitis; evidence also suggests that tonsillectomy at any time in the past results in enhanced susceptibility to the bulbar form of the disease. Recent diphtheria-tetanus-pertussis vaccination increases the likelihood of development of paralysis; the site of injection and the site of paralysis appear to be correlated. Physical exertion and trauma around the time of onset also increase the risk for severe paralysis, especially in adults.

Minor Illness (Abortive Poliomyelitis)

The minor illness is mild and nonspecific, with low-grade fever, malaise, anorexia, and sore throat. Physical examination reveals no significant abnormalities, CSF is normal, and recovery occurs within 24 to 72 hours. The illness often is so mild that it goes unrecognized, and patients rarely are seen by a physician.

Nonparalytic Poliomyelitis (Aseptic Meningitis)

The onset of nonparalytic poliomyelitis is associated with vague malaise followed by fever, headache, aching of the muscles, and sometimes hyperesthesia and paresthesia. Anorexia, nausea, vomiting, constipation, or diarrhea also may be present. The temperature rises to 37.8°C to 39.5°C (101°F–103°F); stiffness of the neck, back, and hamstrings soon appears.

Approximately two-thirds of affected children have a short, symptom-free interlude between the first phase (minor illness) and the second phase (CNS or major illness). This two-phase course occurs less commonly in adults, in whom the evolution of symptoms is more insidious. Nuchal and spinal rigidity is necessary for establishing the diagnosis of nonparalytic poliomyelitis during the second phase.

Physical examination reveals nuchal-spinal signs and changes in superficial and deep reflexes. With cooperative patients, the nuchal-spinal signs are sought first by active tests. The child is asked to sit up unassisted. If doing so causes undue effort, if the knees flex upward, and if the patient writhes a bit from side to side while sitting up and uses the hands on the bed for the tripod supporting position, unmistakable spinal rigidity is present. Still sitting, the patient is asked to flex chin to chest and is observed for nuchal rigidity. Alternatively, from the supine position with the knees held down gently, the patient is asked to sit up and kiss the knees. If the knees draw up sharply or if the maneuver cannot be completed adequately, the patient has stiffness of the spine caused by muscle spasm. If the diagnosis still is uncertain, attempts should be made to elicit the Kernig and Brudzinski signs. Gentle forward flexion of the occiput and neck elicits nuchal rigidity, which may precede spinal rigidity. Head drop may be demonstrated by placing the hands under the patient's shoulders and raising the trunk. Normally, the head follows the plane of the trunk, but in poliomyelitis, it often falls backward limply. The frequency of the head-drop sign, even in nonparalytic poliomyelitis, with no subsequent residuals indicates that it is not caused by true paresis of the neck flexors. In struggling infants, distinguishing voluntary resistance from clinically important involuntary nuchal rigidity may be difficult. One may place the infant's shoulders flush with the edge of the table, support the weight of the occiput in the hand, and then flex the head anteriorly. Nuchal rigidity that persists during this maneuver may be interpreted as involuntary. When not closed, the anterior fontanelle also may be tense or bulging.

In the early stages, the reflexes are normally active and remain so unless paralysis supervenes. Changes in reflexes, either increased or depressed, may precede the onset of weakness by 12 to 24 hours; hence detecting such changes is important, especially in nonparalytic patients managed at home. The superficial reflexes (i.e., cremasteric and abdominal and the reflexes of the spinal and gluteal muscles) are usually the first to be diminished. The spinal and gluteal reflexes are elicited by tapping segmentally downward on each side of the spine and buttocks. These

reflexes may disappear before the abdominal and cremasteric ones. Changes in the deep tendon reflexes, whether exaggerated or depressed, generally occur 8 to 24 hours after depression of the superficial reflexes and indicate impending paresis of the extremities.

Laboratory findings consist of a normal or slightly elevated WBC count and the characteristic CSF changes of aseptic meningitis—approximately 20 to 300 cells, predominantly lymphocytes, a normal glucose level, and a normal or slightly elevated protein level. If a spinal tap is performed in the first few hours after onset, a predominance of polymorphonuclear leukocytes may be seen, but it shifts in 6 to 12 hours to more than 90% lymphocytes. If no further progression of clinical signs occurs, the disease remains nonparalytic, the temperature falls to normal, and signs of meningeal irritation gradually disappear. Recovery ensues in 3 to 10 days, depending on the severity of the illness.

Paralytic Poliomyelitis

The manifestations of paralytic poliomyelitis are those enumerated earlier for nonparalytic poliomyelitis in addition to weakness in one or more muscle groups, either skeletal or cranial. Patients in whom paralysis is destined to develop often wear an anxious expression; they are extremely alert, restless, and flushed and appear acutely ill. The fever is higher than that in abortive disease, and the patient may have intense muscle pain. Shortly before actual muscle weakness is detected, the superficial and deep reflexes often diminish or disappear on the affected side. Frequently, a symptom-free interlude of several days occurs between the initial illness phase and the recurrence of symptoms that culminate in paralysis.

The onset of paralysis may be extraordinarily sudden and may progress in a few hours to complete loss of motion in one or more extremities. Asymmetric involvement is typical in milder cases. More gradual spread of weakness also occurs and may continue over a period of 3 to 5 days. Bladder paralysis of 1 to 3 days' duration develops in approximately 20% of patients, and bowel atony frequently is noted, occasionally to the point of paralytic ileus. In general, when the fever subsides, no further paralysis is likely to occur. The lower limbs are affected more commonly than are the upper, but in severe cases, quadriplegia and loss of function of the intercostal, abdominal, and trunk muscles with resultant respiratory difficulty may ensue. The superficial and deep reflexes in the affected limbs are lost; twitching of the muscles and diffuse fasciculations may be seen transiently. Sensory abnormalities are rare occurrences.

Flaccid paralysis is the most obvious clinical expression of the neuronal changes. The ensuing muscular atrophy is caused by denervation in addition to the atrophy of disuse. The pain, spasticity, nuchal and spinal rigidity, and hypertonia early in the illness probably are caused by lesions in the brainstem, spinal ganglia, and posterior columns. Respiratory and cardiac arrhythmias, blood pressure and vasomotor changes, and similar manifestations reflect damage to vital centers in the medulla.

On physical examination, the distribution of paralysis characteristically is spotty. To detect mild muscular weakness, one often must apply gentle resistance in opposition to the muscle group being tested. The spinal form has weakness of some of the muscles of the neck, abdomen, trunk, diaphragm, thorax, or extremities. The bulbar form is characterized by weakness in the motor distribution of one or more cranial nerves, with or without dysfunction of the vital centers of respiration and circulation. Patients with bulbar disease often are extremely agitated, even delirious, or they may become stuporous. The tenth cranial nerve nuclei are involved most commonly and result in paralysis of the pharynx, soft palate, and vocal cords. Facial paralysis occurs less commonly; it usually is asymmetric and involves only selected muscle groups. Ocular palsies are unusual findings.

Components of both the bulbar and spinal forms occur together in bulbosplinal poliomyelitis. In the encephalitic form of the disease, irritability, disorientation, drowsiness, and coarse tremors not explained by inadequate ventilation are noted. Even during epidemics of poliomyelitis, this form can be recognized only if some peripheral or cranial nerve paralysis coexists or ensues. Hypoxia and hypercapnia caused by inadequate ventilation from respiratory insufficiency may produce disorientation without true encephalitis.

BOX 166.1 Common Sources of Hypoxia and Hypercapnia in Poliomyelitis

1. Cranial nerves IX to XII involved with:
 - a. Pharyngeal paralysis and pooling of secretions
 - b. Laryngeal involvement, either spasm of laryngeal muscles or paralysis of vocal cords
 - c. Lingual paralysis
 - d. Tracheal accumulation of secretions from inability to cough
 - e. Aspiration of vomitus
2. Vital center involvement with:
 - a. Inefficient, irregular respiration
 - b. Cardiovascular disturbance
 - c. Hyperpyrexia causing increased oxygen consumption
3. Cervical and spinal cord involvement causing paresis of the primary and accessory muscles of respiration
4. Pulmonary complications (e.g., pneumonia, atelectasis, and edema)
5. Contributory factors:
 - a. Panic
 - b. Gastric dilation
 - c. Sedation
 - d. Inadequate equipment (e.g., small-bore tracheostomy tubes, unsuitable respirator settings)

From Cherry JD. Enteroviruses. In: Behrman RE, Vaughan VC, eds. *Nelson Textbook of Pediatrics*. 12th ed. Philadelphia: WB Saunders, 1983:791–804.

Numerous components acting together may result in insufficiency in ventilation (Box 166.1). The most serious consequences are hypoxia and hypercapnia, which may produce profound effects on many other systems. Respiratory insufficiency should be detected early to diminish its widespread effects, and because the situation may shift rapidly, continued clinical evaluation is essential. Despite weakness of the respiratory muscles, the patient may respond with so much respiratory effort that normal alveolar ventilation is maintained. In fact, the increased effort (associated with anxiety and fear) actually may produce overventilation at the outset and may result in respiratory alkalosis. Such effort is fatiguing and soon leads to respiratory failure.

For clarity, certain terms characterizing patterns of disease need definition. First, *pure spinal poliomyelitis with respiratory insufficiency* refers to tightness, weakness, or paralysis of the respiratory muscles (chiefly the diaphragm and intercostals) without discernible clinical involvement of the cranial nerves or vital centers. The cervical and thoracic spinal cord segments chiefly are involved. Second, *pure bulbar poliomyelitis* refers to paralysis of the motor cranial nerve nuclei with or without involvement of the vital centers that control respiration, circulation, and body temperature. Involvement of the ninth, tenth, and twelfth cranial nerves is most important because it results in paralysis of the pharynx, tongue, and larynx, with consequent airway obstruction. Third, *bulbosplinal poliomyelitis with respiratory insufficiency* refers to involvement of the respiratory muscles with coexisting bulbar paralysis.

The clinical findings resulting from involvement of the respiratory muscles are as follows: (1) an anxious expression; (2) inability to speak without frequent pauses, a situation resulting in short, jerky, “breathless” sentences that can be demonstrated by asking the child to count numbers serially; (3) increased respiratory rate; (4) movement of the alae nasi and the accessory muscles of respiration; (5) inability to cough or sniff with full depth; (6) paradoxical abdominal movements caused by diaphragmatic immobility from spasm or weakness of one or both leaves; and (7) relative immobility of the intercostal spaces, whether segmental, unilateral, or bilateral. When the arms are weak and especially when deltoid paralysis occurs, one should beware of impending respiratory paralysis because the phrenic nerve nuclei are in adjacent areas of the spinal cord. Observing the patient’s capacity for thoracic breathing while the abdominal muscles are splinted manually can be performed to assess minor degrees of paresis. Light manual

splinting of the thoracic cage helps in evaluating the effectiveness of diaphragmatic movement.

The clinical findings of bulbar poliomyelitis with respiratory difficulty (other than paralysis of the extraocular, facial, and masticatory muscles) include the following:

1. Nasal twang to the voice or cry as a result of palatal and pharyngeal weakness (hard consonant words such as “cookie” or “candy” bring out this condition best).
2. Inability to swallow smoothly that results in an accumulation of saliva in the pharynx and indicates partial immobility (holding the larynx lightly and asking the patient to swallow confirms the immobility).
3. Accumulated pharyngeal secretions, which may cause irregular respiration because each inspiration must be “planned” and cannot be “subconscious” in view of the risk for aspirating; the respirations thus may appear interrupted and abnormal even to the point of falsely simulating intercostal or diaphragmatic weakness.
4. The impossibility of effective coughing, with resultant constant and fatiguing efforts to clear the throat.
5. Nasal regurgitation of saliva and fluids caused by palatal paralysis, with an inability to separate the oropharynx from the nasopharynx during swallowing.
6. Deviation of the palate, uvula, or tongue.
7. Involvement of vital centers, as manifested by an irregularity in the rate, depth, and rhythm of respiration; by cardiovascular alterations that include changes in blood pressure (especially increased), alternate flushing and mottling of the skin, and cardiac arrhythmias; and by rapid changes in body temperature.
8. Paralysis of one or both vocal cords that causes hoarseness, aphonia, and, ultimately, asphyxia unless recognized by laryngoscopy and managed by immediate tracheostomy.
9. The “rope sign,” an acute angulation between the chin and larynx caused by weakness of the hyoid muscles (the hyoid bone is pulled posteriorly, thus narrowing the hypopharyngeal inlet).

Myocardial failure sometimes develops secondary to pulmonary complications or as a result of acute myocarditis. The initial manifestation of poliovirus infection on occasion can resemble that of Guillain-Barré syndrome.¹²⁰¹

Congenital Infections

Abortion

Poliomyelitis is associated with an increased incidence of abortion. Horn⁴⁹⁸ noted 43 abortions in 325 pregnancies complicated by maternal poliomyelitis. Abortion was related directly to the severity of the maternal illness, including the degree of fever during the acute phase of illness. However, abortion also has occurred in association with mild nonparalytic poliomyelitis. Greenberg and Siegel⁴²⁸ noted that fetal death occurred in 14 of 30 instances (46.7%) of maternal poliomyelitis during the first trimester. Kaye and associates⁶⁰³ reviewed the literature in 1953 and recorded 19 abortions in 101 cases of poliomyelitis in pregnancy. In a small study in Evanston Hospital in Illinois, the abortion rate in maternal poliomyelitis was little different from the expected rate.¹¹¹

Congenital Malformations

Although isolated instances of congenital malformation and maternal poliomyelitis have been noted, little statistical evidence supports the suggestion that polioviruses are teratogens. In their review of the literature, Kaye and colleagues⁶⁰³ noted 6 anomalies in 101 infants born to mothers with poliomyelitis during pregnancy. In the reviews of Horn,⁴⁹⁸ Bates,⁶⁷ and Greenberg and Siegel,⁴²⁸ no evidence of maternal polioviral infection–induced anomalies was found. Similarly, no evidence suggests that infection with poliovirus vaccine during pregnancy causes congenital malformations.⁴⁶⁰

Prematurity and Stillbirth

In Horn’s study⁴⁹⁸ of 325 pregnancies, nine infants died in utero. In each instance, the mother was critically ill with poliomyelitis. Horn⁴⁹⁸ also noted that 45 infants weighed less than 6 pounds, and 17 of them had a birth weight less than 5 pounds. These low-birth-weight infants were born predominantly to mothers who had poliomyelitis early in

pregnancy. In New York City, Greenberg and Siegel⁴²⁸ also noted an increase in prematurity after maternal poliomyelitis infection. It was related specifically to maternal paralytic poliomyelitis.

Neonatal Infections

General Infections

In the excellent review by Bates⁶⁷ in 1955, 58 cases of poliomyelitis in infants younger than 1 month were described. Although complete data were not available on many of the cases, 51 had paralysis, died of their disease, or both. Of the total number of infants on whom these investigators had clinical data, only one infant had nonparalytic disease. More than one-half of the cases were secondary to maternal disease. Because other investigators have noted congenital infection without symptomatic maternal infection, infection in the mother probably was the source for an even greater percentage of the neonatal illnesses. The incubation period of neonatal poliomyelitis has not been established, and, therefore, determining how many of the babies were infected in utero is difficult. Probably, most illnesses that occurred within the first 5 days of life were congenital. Most of the neonates had symptoms of fever, anorexia or dysphagia, and listlessness. Almost one-half of the infants noted in this review died, and of those surviving, 48% had residual paralysis.

Infection Acquired in Utero

Elliott and associates³³¹ described an infant girl in whom “complete flaccidity” was noted at birth. This child’s mother had mild paralytic poliomyelitis, with the onset of minor illness occurring 19 days before the infant’s birth. Fetal movements had ceased 6 days before delivery, a finding suggesting that paralysis had occurred at this time. On examination, the baby was severely atonic; when supported under the back, she was passively opisthotonic. Respiratory efforts were abortive and were confined to the accessory muscles; laryngoscopy revealed complete flaccidity in the larynx.

Johnson and Stimson⁵⁷⁵ reported a case in which the mother’s probable abortive infection occurred 6 weeks before the birth of the baby. The baby initially was thought to be normal but apparently underwent no medical examination until the fourth day of life. At this time, the physician noted right hemiplegia. On the following day, a more complete examination revealed lateral bulging of the right side of the abdomen accompanied by crying and maintenance of the lower extremities in a frog leg position. Adduction and flexion at the hips were weak, and the knee and ankle jerks were absent. Laboratory studies were unremarkable except for examination of CSF. It revealed 20 lymphocytes and a protein level of 169 mg/dL. During a 6-month period, this child’s paralysis gradually improved and resulted in only residual weakness of the left lower extremity.

Paresis of the left arm was noted shortly after birth in another child with apparent transplacentally acquired poliomyelitis.⁷²⁴ At 2 days of age, the baby was quadriplegic, but patellar reflexes were present, and the child had no respiratory or swallowing difficulties. This child had pneumonia at 3 weeks of age, but otherwise, general neurologic improvement occurred. Examination at 8 weeks of age revealed bilateral atrophy of the shoulder girdle muscles. The CSF from this patient had 63 leukocytes/mm³, 29% of them polymorphonuclear cells, and a protein concentration of 128 mg/dL.

All three of the infants just discussed apparently were infected in utero several days before birth. Their symptoms were exclusively neurologic; fever, irritability, and vomiting did not occur.

Postnatally Acquired Infection

In contrast to infections acquired in utero, those acquired postnatally are more typical of classic poliomyelitis. Shelokov and Weinstein¹⁰²⁵ described a child who was asymptomatic at birth. The onset of minor symptoms in the mother occurred 3 weeks before delivery, and the onset of major symptoms occurred 1 day before delivery. On the sixth day of life, the infant suddenly became ill with watery diarrhea. He looked grayish and pale. On the following day, he was irritable, lethargic, and limp and had a temperature of 38°C (100.4°F). Mild opisthotonos and weakness of both lower extremities developed. He was responsive to sound, light, and touch. The CSF had an elevated protein level and an increased number of leukocytes. His condition worsened during a

total period of 3 days, and then gradual improvement began. At 1 year of age, he had severe residual paralysis of the right leg and moderate weakness in the left leg.

Baskin and associates⁶⁶ described two infants with neonatal poliomyelitis. The first child, whose mother had severe poliomyelitis at the time of delivery, was well for 3 days and then had a temperature of 38.3°C (100.9°F). On the fifth day of life, the boy became listless and cyanotic. Examination of CSF revealed a protein level of 300 mg/dL and 108 leukocytes/mm³. His condition worsened, and extreme flaccidity, irregular respiration, and progressive cyanosis developed; he died on the seventh day of life. The second infant was a boy who was well until he was 8 days old but then became listless, with a temperature of 38.38°C (101.08°F). During the next 5 days, flaccid quadriplegia developed, as did irregular, rapid, and shallow respirations and an inability to swallow. The child died on the 14th day of life. Acute poliomyelitis had developed in his mother 6 days before the onset of his symptoms.

Abramson and colleagues⁵ reported four children with neonatal poliomyelitis, two of whom died. In three of the children, the illnesses were typical of acute poliomyelitis in older children. The other child died at 13 days of age with generalized paralysis. The onset of his illness was difficult to define, and he was never febrile. Bates⁶⁷ described infants with acute poliomyelitis and clinical illnesses similar to those that occur in older persons.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Clinical Diagnosis

Clinical differentiation of enteroviral disease frequently is thought to be impossible. Although treatable bacterial illnesses always should be considered and treated first, it is also true that when all the circumstances of a particular illness are considered, enteroviral diseases can be suspected on clinical grounds. The most important factors in clinical diagnosis are the season of the year, geographic location, exposure, incubation period, and clinical symptoms.

In temperate climates, the prevalence of EVs is distinctly seasonal, so disease usually is seen in the summer and fall. Enteroviral disease is less likely to occur in the winter. In the tropics, EVs are prevalent throughout the year, and the season therefore is not diagnostically helpful.

As with all infectious illnesses, knowledge of exposure and incubation time is important. A careful history of maternal illness is critical in neonatal disease. For example, nonspecific, mild febrile illness in a mother that occurs in the summer and fall should warn of the possibility of severe neonatal illness. Specific findings (i.e., aseptic meningitis, pleurodynia, herpangina, pericarditis, myocarditis) should alert the clinician to enteroviral illnesses. The short incubation period of enteroviral infections should be considered.

Laboratory Diagnosis

Virus Isolation and Detection Techniques

Most viral diagnostic laboratories have facilities for the recovery of most EVs that cause illness. A three-tissue culture system that includes primary monkey kidney, a diploid, human embryonic lung fibroblast cell strain, and the RD cell line will allow the isolation of virtually all group B coxsackieviruses and echoviruses and some coxsackieviruses A (e.g., coxsackieviruses A9 and A16). In a study in which Buffalo green monkey kidney cells and subpassage of primary human embryonic kidney cells were used in addition to primary monkey kidney and human diploid fibroblast (MRC-5) cells, the recovery rate of EVs was increased 11%.²¹⁰ For a complete diagnostic isolation spectrum, suckling mouse inoculation also should be performed.

Proper selection and handling of specimens are most important in the isolation of viruses. Enteroviral infections tend to be generalized, so collection of material from multiple sites is important; specimens should be collected from any or all of the following: nasopharynx, throat, stool, blood, urine, CSF, and any other body fluids that are available. Swabs from the nose, throat, and rectum should be placed in a carrying medium containing a small amount of protein. Hanks balanced salt solution with 2% agamma calf serum and antibiotics is satisfactory. Fluid specimens should be collected in sterile vials; specimens of postmortem material are collected best in vials that contain carrying

medium. In general, specimens should be refrigerated immediately after collection and during transportation to the laboratory. The specimens must not be exposed to sunlight during transportation. If an extended period will elapse before a specimen is processed in the laboratory, shipping and storing it frozen are advisable.

Contrary to popular belief, tissue culture evidence of enteroviral growth takes only a few days in many cases and less than a week in most.⁴²⁶ The use of spin amplification, the shell vial technique, and monoclonal antibodies has been shown to reduce the time of detection in enteroviral cultures significantly.^{640,896,1023,1096} After an EV has been isolated, type identification is performed conventionally by neutralization, and this process, unfortunately, frequently takes a long time.

Nucleic acid techniques with cDNA and RNA probes have been shown to be useful for direct identification of EVs.^{144,285,526,533,898,964,965,96}

⁷ Most important, however, has been the development of numerous PCR techniques. Since 1990, many reports have described enteroviral, parechoviral, and SAFV PCR methods and their use in identifying viral RNA in clinical specimens.*

PCR has proved most useful for the direct identification of EVs and PeVs in the CSF of patients with meningitis.^{34,526,970,996,1074,1086,1197} When compared with culture of CSF specimens, PCR is faster and more sensitive and the specificity is equal.

PCR also has proved useful in the identification of EVs and PeVs in blood, urine, and throat specimens.^{10,24,133,835,838,1021,1053} Particularly impressive are the findings of Byington and associates^{119,133} and Rittichier and associates.⁹⁵² Using PCR on specimens of blood and CSF, these investigators found that more than 25% of infants admitted to the hospital for suspected sepsis in 1997 had nonpolio enteroviral infections. On the basis of this study and the work of Andréoletti and coworkers,²⁴ we consider that the general workup for febrile children hospitalized for possible sepsis should include PCR for EVs and PeVs in both blood and CSF, if available. A shortcoming of PCR is that EV RNA is identified, but a specific enteroviral type is not. Because of this shortcoming, we recommend that conventional culture be performed in addition to PCR. However, in the research setting, further molecular study often can identify the genotype of a causative agent from the original sample submitted for PCR assay.⁶²¹

EV RNA also has been identified in numerous tissue specimens from patients with chronic medical conditions such as idiopathic DCM. However, as discussed earlier in the section on cardiovascular manifestations, the possibility of a lack of specificity (false-positive results) is a concern. Polioviruses can be separated from other EVs, and poliovirus vaccine strains can be identified rapidly by PCR.^{4,216,323,1194}

Serology

Except in special circumstances, the use of serologic techniques for establishing the primary diagnosis of suspected enteroviral infection is impractical. Standard serologic study depends on the demonstration of a rise in antibody titer to a specific virus as an indication of infection with that agent. Although enzyme-linked immunosorbent assay, hemagglutination inhibition, and complement fixation take only a short time to perform, these tests can be carried out only after a second, convalescent-phase blood specimen has been collected. These tests also are impractical in searching for the cause of a specific illness in a child because of the existence of so many antigenically different EVs. As noted previously in the discussion of antigenic characteristics, group antigens can be produced that allow one to establish a serologic diagnosis by IgM enzyme immunoassay and complement fixation, but these tests lack specificity.^{989,1082,1083}

In the evaluation of a patient with a suspected enteroviral infection, serum should be collected as soon as possible after the onset of illness and then again 2 to 4 weeks later. This serum should be stored frozen. In most clinical situations, performing serologic tests on the collected serum is not necessary because demonstration of a rise in antibody

*References 4, 10, 24, 29, 50, 84, 133, 216, 246, 247, 251, 323, 364, 377, 423, 453, 534, 621, 660, 667, 699, 739, 765, 810, 835, 846, 849, 866, 928, 952, 956, 963, 966, 970, 993, 1001, 1020, 1021, 1026, 1034, 1052, 1064, 1073, 1074, 1086, 1102, 1126, 1129, 1134, 1182, 1194, 1197.

titer in the serum of an infant from whom a specific virus has been isolated from a body fluid obviously is superfluous. However, collected serum can be useful diagnostically if the prevalence of specific EVs in a community is known. In this situation, looking for antibody titer changes to a selected number of viral types is relatively easy. Faster diagnosis can be made with a single serum sample if a search for specific IgM enteroviral antibody is made.^{175,227,390,408,409,420,1027,1101,1219}

Unfortunately, no EV IgM antibody tests are commercially available in the United States. Commercial laboratories offer enteroviral complement fixation antibody panels. However, these tests are expensive, and their results in the clinical setting almost always are meaningless unless acute-phase and convalescent-phase sera are analyzed.

Histology

Enteroviral infections have no specific histologic findings such as those seen in cytomegalovirus or HSV infection. However, tissues can be examined for specific enteroviral antigens by immunofluorescence and for RNA by PCR.^{129,171,738}

Differential Diagnosis

The differential diagnosis of enteroviral infection depends on the clinical manifestations. In general, the most important considerations relate to bacterial diseases such as those commonly associated with pharyngitis, pneumonia, pericarditis, meningitis, and septicemia. Other viruses must be considered with upper respiratory tract illnesses, gastrointestinal infections, rashes, encephalitis, and neonatal illness.

Paralytic poliomyelitis usually presents no diagnostic problem in the presence of an outbreak, but sporadic cases are another matter, especially in countries such as the United States, where the disease (except for the vaccine-associated form) has disappeared and many pediatricians have never seen a case. Rarely, other EVs have been shown to cause paralytic syndromes that are indistinguishable from poliomyelitis.

Several other diseases must be considered in the differential diagnosis of sporadic cases of paralytic illness. Guillain-Barré syndrome is the most common and difficult differential diagnostic problem. Fever, headache, and meningeal signs usually occur less commonly in Guillain-Barré syndrome; the paralysis characteristically is symmetric, and sensory changes are common findings. Also in Guillain-Barré syndrome, the CSF contains few cells but a significant elevation in protein concentration. Other illnesses confused with paralytic poliomyelitis include peripheral neuritis (postinjection, toxic, herpes zoster), arboviral infection, rabies, tetanus, botulism, and tick paralysis.

TREATMENT

Specific Therapy

No specific therapy for any enteroviral infection is approved for use in the United States. In severe, catastrophic, and generalized neonatal infection, in all probability the baby received no specific antibody for the particular virus from the mother. In this situation, administering immunoglobulin to the infant is advisable because high titers of neutralizing antibody to most EVs and PeVs frequently are present in immunoglobulin.^{16,235,274,1215} Little evidence supports the claim that this therapy is beneficial; however, it can be expected to stop further organ seeding secondary to continued viremia. Intravenous or intraventricular injection of immunoglobulin with IVIG and administration of hyperimmune plasma have been useful on some occasions and not others in the treatment of enteroviral infection in patients with agammaglobulinemia.*

Abzug and associates⁸ performed a small but controlled study in which nine EV-infected neonates received IVIG and seven similarly infected infants received supportive care. In this study, no significant difference was found in clinical scores, antibody values, or the magnitude of viremia and viruria in those treated versus control infants. However, five infants received IVIG with a high neutralizing antibody titer (>1:800) to their individual viral isolates, and they experienced faster cessation of viremia and viruria. A neonate with disseminated echovirus 11

infection and hepatitis, pneumonitis, meningitis, DIC, decreased renal function, and anemia who survived after receiving a large dose of IVIG and supportive care was described.⁵⁷⁷ Administering IVIG to older children with life-threatening enteroviral infection also seems reasonable. A specific recommended dosage is unknown, but 400 mg/kg per day for 4 days or 2 g/kg in one dose has been used.

Jantausch and associates⁵⁶¹ reported an infant with a disseminated echovirus 11 infection who survived after receiving maternal plasma transfusions. A neonate with fulminant echovirus 11 infection survived after undergoing orthotopic liver transplantation.²⁴¹

The antiviral drug pleconaril offers promise for the treatment of enteroviral infections.* This drug is a novel compound that integrates into the capsid of EVs. It prevents virus attachment to cellular receptors and the uncoating and subsequent release of viral RNA into the host cell. In a double-blind, placebo-controlled study of 39 patients with enteroviral meningitis, a statistically significant shortening of duration of disease was noted—from 9.5 days in control subjects to 4.0 days in drug recipients.⁹⁶⁹ Pleconaril also has been used on a compassionate-release basis for the treatment of patients with life-threatening infection.^{69,125,971} The following categories of enteroviral illness have been treated: chronic meningoencephalitis in patients with agammaglobulinemia or hypogammaglobulinemia, neonatal sepsis, myocarditis, poliomyelitis (wild-type or vaccine associated), and encephalitis, as well as in bone marrow transplant recipients. Although these treatment studies did not have control arms, favorable clinical responses were observed in 26 of 50 treated patients, including 12 of 18 patients with chronic meningoencephalitis.

In subsequent randomized double-blind studies, 240 immunocompetent adolescents and adults with confirmed EV meningitis received pleconaril or placebo.²⁹⁵ Post hoc analysis revealed that pleconaril-treated subjects reported headaches for a shorter period; no other differences in outcome were observed. The results of a lengthy double-blind placebo-controlled trial of pleconaril for the treatment of neonates with EV sepsis were published.^{11,791} In intent-to-treat analysis, deaths were less common in pleconaril-treated infants than placebo recipients (10 of 43 [23%] vs. 8 of 18 [44%]; $P = .02$), but the differences in mortality rates of children with proven EV infection were not significantly different (7 of 31 [23%] vs. 5 of 12 [42%]; $P = .26$). The small study size of the study, low serum concentrations of pleconaril in the first 24 hours of treatment, and other factors make it difficult to assess the therapeutic potential of pleconaril in neonates. The investigators called for additional studies on the basis of evidence of viral suppression and other statistical signals suggesting drug efficacy.

The activity of pleconaril against EV D68 was evaluated using the reference Fermon strain and more recent 2014 isolates.^{709,947} Although the reference strain was quite sensitive, the newer strains required much higher concentrations for inhibition.

Investigations of other antiviral agents are ongoing, driven both by the need for treatment options for nonpoliovirus EVs and by the proposal that antiviral agents may be needed to ensure eradication of poliovirus circulation.²⁵³ Other capsid-binding agents exist, including pirodavir and vapendavir, and these exhibit activity against EV 71 and poliovirus strains.⁷ However, clinical experience with these agents is very limited, and none had significant antiviral activity against the strains of EV D68 that circulated in 2014.⁹⁴⁷ Other novel specific inhibitors of EV have been identified. However, progress toward the clinical studies has been impeded by limited antiviral activity, poor bioavailability, intrinsic resistance by some circulating strains, and pharmacoeconomic considerations.⁷

In severe illnesses such as neonatal myocarditis or encephalitis, a frequent temptation is to administer corticosteroids. Although some workers have thought that this therapy is beneficial in treating coxsackieviral myocarditis, we recommend that corticosteroids not be given during acute enteroviral infection. The deleterious effects of these agents in coxsackieviral infection of mice are particularly persuasive factors in this opinion.^{106,629} Immunosuppressive therapy for myocarditis of unknown origin with prednisone and cyclosporine or azathioprine was

*References 12, 103, 264, 319, 335, 382, 448, 480, 751, 762, 766, 1120, 1153.

*References 11, 69, 125, 295, 604, 709, 718, 899, 947, 969, 971, 1150.

evaluated in a controlled trial of 111 adults, but no beneficial effect was observed.⁷⁴¹

Because the possibility of bacterial sepsis cannot be ruled out in many instances of enteroviral infection, antibiotics frequently should be administered for the most likely potential pathogens. Care in the selection and administration of antibiotics is urged so that drug toxicity is not added to the problems of the patient.

Nonspecific Therapy

Mild, Nonspecific Febrile Illness

In patients in whom fever is the only symptom, careful observation is important. Many patients who eventually become severely ill initially have 2 to 3 days of fever without other localized findings. Care should be taken to administer adequate fluids to febrile infants, and excessive elevation of temperature should be prevented if possible.

Myocarditis

Myocarditis has no specific therapy. However, congestive heart failure and arrhythmias occur, and they should be treated by the usual methods. In administering digitalis to patients with enteroviral myocarditis, paying careful attention to the initial dosage is most important because the heart often is extremely sensitive; frequently, only small amounts of digoxin are necessary.

Meningoencephalitis

In patients with meningoencephalitis, seizures, cerebral edema, and disturbances in fluid and electrolyte balance all occur frequently and respond to treatment. Seizures are treated best with phenobarbital, phenytoin, or lorazepam. Cerebral edema can be treated with urea, mannitol, or large doses of corticosteroids. As noted, the use of corticosteroids in patients with active enteroviral infection seems unwise because the local benefit may be outweighed by the overall deleterious effects. Fluids should be monitored closely, and serum electrolyte levels should be determined frequently because inappropriate antidiuretic hormone secretion is a common occurrence.

Poliomyelitis

The broad principles of management are to allay fear, minimize the ensuing skeletal deformities, anticipate and meet complications in addition to the neuromusculoskeletal ones, and prepare the child and family for the prolonged treatment that may be required and for permanent disability when it seems likely. Patients with the non-paralytic and mildly paralytic forms of the disease may be treated at home.

Most patients with paralytic poliomyelitis require hospitalization. A calm atmosphere is desired. Suitable body alignment is necessary to avoid excessive skeletal deformity. A neutral position with the feet at a right angle, knees slightly flexed, and hips and spine straight is achieved by the use of boards, sandbags, and, occasionally, light splint shells. Active and passive motion is indicated as soon as the pain has disappeared. The orthopedist and physiatrist should see these patients as early in the illness as possible and should assume responsibility before fixed deformities develop.

Management of pure bulbar poliomyelitis consists essentially of maintaining the airway and avoiding all risks for inhalation of saliva, food, or vomitus. Gravity drainage of accumulated secretions is favored by the head-low (foot of the bed elevated 20 to 25 degrees), prone position with the face to one side. Aspirators with rigid or semirigid tips are preferred for direct oral and pharyngeal use, and soft flexible catheters may be used for nasopharyngeal aspiration. Fluid and electrolyte balance is maintained best by intravenous infusion because tube or oral feeding in the first few days may incite vomiting. After the initial few days, sips of sterile water may be given from a spoon, with increments as indicated by the child's ability to swallow. In addition to close observation for respiratory insufficiency, blood pressure should be recorded at least twice daily. Hypertension is not uncommon and occasionally leads to hypertensive encephalopathy. Patients with pure bulbar poliomyelitis may require tracheostomy because of paralysis of the vocal cords or constriction of the hypopharynx. Most patients with pure bulbar poliomyelitis who recover have little residual impairment; some patients

exhibit mild dysphagia and occasional vocal fatigue with slurring of speech.

Impaired ventilation must be recognized early; mounting anxiety, restlessness, and fatigue are early indications for prompt intervention. Tracheostomy is indicated for some patients with pure bulbar poliomyelitis, spinal respiratory muscle paralysis, and bulbospinal paralysis. Unlike other patients on whom tracheostomy is performed, these patients generally are unable to cough, sometimes for many months. Frequent and swift endotracheal aspiration under aseptic conditions is necessary. Mechanical ventilation often is needed. Patients are fully conscious and aware; terrifying procedures are performed best with an outward atmosphere of calm. Explaining the procedure and having the parents on hand may be helpful. A reduction in thoracic compliance occurs early, and higher than expected pressure gradients may be required to achieve adequate ventilation. Weaning a patient from dependence on respiratory assistance is a torturous process, as is total musculoskeletal rehabilitation. Motivation of the patient and the team of personnel is paramount.

PROGNOSIS

The prognosis for nonpolio enteroviral infections is excellent in most instances. Virtually all morbidity and mortality are related to cardiac and neurologic diseases in older children and to these diseases in addition to general disseminated infection with hepatitis in neonates.

The prognosis for poliomyelitis varies with the degree of muscle involvement. In patients with mild muscle weakness, complete recovery is the rule. If paralysis is present, recovery of muscle function continues for a period of approximately 18 months to 2 years. By 3 months, approximately 60% of the ultimate improvement has been achieved, and by 6 months, 80%. The final result depends on the extent and localization of nerve cell damage.

Respiratory failure is responsible for most of the deaths in paralytic poliomyelitis. With the many improvements in techniques for handling this complication, the overall mortality rate has been reduced to approximately 4%; with the bulbar form and in adults, it still may be as high as 10%.

Occasionally, new neuromuscular symptoms develop later in life in patients who have had paralytic poliomyelitis.^{145,276,277,568,929,1087,1175,1174} Although the cause of this late-onset weakness and muscle atrophy (postpolio syndrome) is not understood completely, it most likely is the result of routine attrition of anterior horn cells associated with aging rather than persistent neural infection with polioviruses. However, specific immunopathologic mechanisms possibly play a role in some instances.⁴⁰⁵

Leparc-Goffart and associates⁶⁸¹ presented data suggesting the presence of poliovirus-specific genomic sequences in the CSF of patients with postpolio syndrome. However, Muir and colleagues,⁸¹² who performed similar studies, found no association of chronic neurologic disease with the presence of enteroviral RNA in CSF.

PREVENTION

Nonpolio Enteroviral Vaccines and Immune Globulin

Until recently no attenuated or live viral vaccines for EVs other than polioviruses were available. Because of its epidemic nature and disease severity, vaccines for EV 71 have been developed.^{230,1217} The developed vaccines have been found to be safe and effective. In three different vaccine trials in children (6–60 months of age), an efficacy of greater than 90% against EV 71 hand-foot-and-mouth disease and greater than 80% against more serious diseases (CNS manifestations and hemorrhagic pulmonary edema) was observed.²³⁰ Two of the vaccines have been approved for marketing in China.¹²¹⁷

Passive protection is IVIG may be useful in preventing disease. In practice, however, it would seem worthwhile only for sudden and virulent nursery outbreaks. For example, if several cases of myocarditis occurred in a nursery, administering IVIG to all babies in the nursery would seem reasonable. Pooled human immunoglobulin in most instances can be expected to contain antibodies against coxsackieviruses B1, B2, B3, B4, and B5, as well as several coxsackieviruses A, echoviruses, other

EVs, and PeVs 1,3, and 6.^{16,274,1215} Therefore, this procedure would offer protection to infants without transplacentally acquired specific antibody who had not yet become infected. Immune serum was useful in the management of three nursery enteroviral outbreaks.^{143,817,890}

Polioviral Vaccines

In the United States, the total annual number of paralytic cases fell from an average of 16,000 in the 5 years before the introduction of vaccine to approximately 10 cases per year between 1980 and 1984. The experience in 1979, however, when 26 paralytic cases were reported, served as a reminder that virulent polioviruses still could surface in susceptible persons.^{152,151} Most of the 1979 cases occurred in Pennsylvania and several other states in Amish population groups who had not been immunized. A similar epidemic in Connecticut in 1972 involved a pocket of unimmunized students in a Christian Science school.¹⁴⁸ These outbreaks reflected the reality that poliomyelitis was still occurring in many parts of the world. The possibility of the introduction of virulent strains was ever present, and only through continued and extensive immunization programs could the disease be prevented from reappearing in epidemic form.⁵⁰³

The remarkable overall record of the decline in paralytic poliomyelitis in the United States was a result of the development and use of two effective vaccines.^{503,1063,1130} IPV, the first to be licensed, was used extensively beginning in 1955 and considerably reduced the incidence of the disease, although epidemics continued to occur. Live-attenuated OPV, licensed in 1961 and 1962, subsequently was recommended as the method of choice in the United States on the basis of its superiority in terms of immunogenic capacity, ability to induce local IgA antibody in the oropharynx and intestinal tract and thus provide greater resistance to reinfection, and ease of administration. OPV gradually supplanted IPV, and between 1973 and 1978, it was the only vaccine available. Its extraordinary effectiveness at that time, despite reaching only 65% of children younger than 5 years of age with the recommended three doses, suggested that the capacity of the attenuated strains to spread contributed to a much higher immunization rate than was indicated by vaccination statistics. The potential impact of such spread on the immunity of the population was illustrated by the observations of Fox and Hall,³⁶⁵ who conducted long-term virologic surveillance of middle-income families in Seattle, Washington. Polioviruses (vaccine strains) accounted for 50% of the 2937 viral isolates from healthy children, their parents, and others in the community. In an analysis of 611 of the poliovirus isolates, researchers found that 75.6% were from vaccinees, 10.5% were from vaccinee contacts, and 14% were from persons without recent known contact with vaccine or a vaccinee. These findings provided a vivid picture of the pervasiveness of the attenuated strains and their continuous circulation in the population. This feature also was supported by the almost invariable recovery of polioviruses from weekly samples of sewage that were collected throughout the year, in the early vaccine era, in urban communities.⁵⁰⁴

Despite its striking success, the oral vaccine had some problems. One was greatly reduced seroconversion rates when the vaccine was given to children living in the tropics: as few as 50% had satisfactory responses, in contrast to the more than 95% response rate in the United States and similar countries.^{502,770} Viral interference from other EVs played some role, and the presence of an inhibitory substance in the oropharynx that prevented significant multiplication of the vaccine strains also was involved. The seroconversion problem was lessened by using pulse immunization programs.^{567,980} For example, the strategy of national annual vaccination days twice per year, 2 months apart, has been successful in developing countries.

Another problem with OPV—and the major problem in the United States—was the occurrence of a small number of vaccine-associated cases of poliomyelitis.^{503,770} The immunogenic effectiveness of the vaccine depends on multiplication of the attenuated strains in the intestinal tract. Because no poliovirus strain is completely stable, the progeny of vaccine strains underwent a certain degree of mutation, which rarely resulted in increased virulence and vaccine-associated cases in recipients and their contacts, most often their parents.

Since 1980, no indigenous cases of wild poliovirus disease have occurred in the United States.^{158,1056} From 1980 to 1989, 80 cases of

vaccine-associated paralytic poliomyelitis and five cases of imported disease were reported. The overall rate of vaccine-associated paralytic poliomyelitis was one case per 2.5 million doses of distributed vaccine; the risk for recipients was one case per 6.8 million doses, and for household contacts it was one case per 6.4 million doses. Of the 80 cases, 30 occurred in vaccinees, 32 occurred in household contacts, four were community acquired, and 14 occurred in immunologically abnormal persons.

Further analysis revealed that the risk associated with the first dose of vaccine was one case per 700,000 doses, but it was only one case per 6.9 million for subsequent doses; for vaccine recipients, the calculated risks were one case per 1.4 million initial doses and one case per 41.5 million subsequent doses. The calculated risks for contact cases were one case per 1.9 million initial doses of vaccine and one case per 13.8 million subsequent doses.

Immunodeficient children are at particular risk for acquiring vaccine-associated paralytic poliomyelitis.^{149,1056} From 1969 through 1976, 11% of vaccine-associated cases occurred in immunodeficient patients; 10 of 11 of these patients were children younger than 1 year. From 1980 to 1989, 18% of vaccine-associated paralytic poliomyelitis cases occurred in immunodeficient patients.¹⁰⁵⁶

Although the risks mentioned earlier were considered acceptable in view of the benefits provided, the question raised repeatedly since the 1970s was whether the United States should return to the use of IPV, which does not carry a risk for acquiring paralytic disease and has been highly successful in several small European countries in which more than 95% of the population is immunized.^{363,378,490,583,601,815,884,983–986,1056}

The problem was reviewed in detail by a committee of the Institute of Medicine (IOM) of the National Academy of Sciences, which reported its recommendations in April of 1977.⁸⁴⁰ The conclusion at the time was that given the situation in the United States, in which not more than 65% of susceptible children were vaccinated, OPV should continue to be the principal vaccine for routine immunization. IPV, conversely, should be provided for two groups: immunodeficient persons, because of their greatly enhanced risk for acquiring vaccine-associated disease after receiving the oral vaccine; and adults receiving primary immunization, because of their greater susceptibility to paralytic disease. Also suggested was that the inactivated vaccine be available as an alternative for those who prefer it. In addition, a single dose of trivalent OPV was suggested for all entrants into the seventh grade of school as a means of added protection for later years when they became parents.

In January of 1988, a panel appointed by the IOM again reviewed policy options for vaccination against poliomyelitis in the United States.⁵⁴¹ The IOM panel concluded that no change in policy should be recommended at that time. However, they did recommend that a new enhanced IPV replace the old vaccine when inactivated vaccine was indicated. They also suggested that when a new enhanced diphtheria-tetanus-pertussis IPV became available, a regimen of two or more doses of it followed by the oral vaccine be considered.

In 1996, the US poliovirus vaccine immunization program was evaluated extensively by both the Advisory Committee on Immunization Practices (ACIP) and the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP). The ACIP recommended that sequential administration of IPV followed by OPV be the schedule of choice in the United States (W.A. Orenstein, personal communication, 1996). The schedule consisted of two doses of the inactivated vaccine at 2 and 4 months of age and two doses of the oral vaccine at 12 to 18 months and 4 to 6 years of age. Both committees indicated that schedules that include all the doses of each vaccine also were acceptable (R.E. Hanneman, personal communication, 1996; W.A. Orenstein, personal communication, 1996). At the present time, an all-IPV vaccination schedule is recommended in the United States.^{23,784} It is a four-dose schedule with doses at 2 and 4 months, 6 to 18 months, and 4 to 6 years. The reader is advised to consult the recommendations of the ACIP and the AAP, as well as the manufacturers' literature, for full consideration of the contraindications and indications for poliovirus vaccines.

Routine primary poliovirus vaccination of adults older than 18 years is not conducted in the United States. However, adults at risk for exposure

to wild polioviruses (i.e., laboratory workers, international travelers, health care workers) should be immunized. For the vaccination of adults, IPV is recommended. Patients with immunodeficiency diseases should not be given OPV; live virus also should not be used in households in which an immunodeficient person resides.

Global Eradication of Poliomyelitis

The WHO established the Expanded Program on Immunization (EPI) in 1974.^{528,1145,1187} Subsequently, the use of OPV in developing countries vastly increased. In 1980 in Brazil, researchers demonstrated that mass administration with the oral vaccine on National Immunization Days (NIDs) led to a dramatic reduction in the incidence of poliomyelitis.²⁹¹ This demonstration led in 1985 to the targeted eradication of poliomyelitis from the Western Hemisphere by 1990. This campaign was successful in that the last confirmed case of paralytic poliomyelitis caused by wild poliovirus occurred in 1991 in Peru.¹⁵² In September 1994, an international commission convened by the Pan American Health Organization certified that indigenous transmission of wild poliovirus had been interrupted in the Americas.¹⁵⁷

In 1988, the World Health Assembly established the objective of global eradication of polio by 2000.⁵²⁸ This program was based on four strategies recommended by the WHO: (1) maintenance of high vaccination coverage levels among children with at least three doses of OPV; (2) development of sensitive systems of epidemiologic and laboratory surveillance, including use of the standard WHO case definition (i.e., a confirmed case of poliomyelitis is defined as acute flaccid paralysis and at least one of the following: laboratory-confirmed wild poliovirus infection, residual paralysis of 60 days, death, or no follow-up investigation at 60 days); (3) administration of supplementary doses of OPV to all young children (usually those <5 years) during NIDs to interrupt the transmission of poliovirus rapidly; and (4) “mopping up” vaccination campaigns, which are localized campaigns targeted at high-risk areas where wild poliovirus transmission was most likely to persist at low levels. NIDs are mass campaigns conducted over the course of a short period (i.e., days to weeks) during which two doses of OPV are administered to all children in the target age group regardless of previous vaccination history, with an interval of 4 to 6 weeks between doses.

From 1985 through 1990, worldwide routine vaccination coverage levels increased from 47% to 85% and stabilized at 80% to 81% from 1991 to 1994.¹⁵⁸ From 1985 through 1994, the number of cases reported annually decreased 84%, from 39,361 to 6241. The number of countries reporting polio cases decreased steadily from 1985 (99 of 196 [51%]) to 1988 (88 of 196 [45%]) and 1994 (51 of 214 [24%]). In addition, the number of countries reporting zero polio cases increased from 1985 (84 [43%]) to 1988 (104 [53%]) and 1994 (145 [68%]). The number of countries with endemic polio that conducted NIDs each year increased from 15 in 1988 to 37 in April of 1995; 24 additional countries scheduled their first NIDs for later in 1995.

At the beginning of the 21st century, NIDs had been conducted in every country in the world with endemic polio. In 1999, 7141 cases of poliomyelitis were reported worldwide. These cases occurred in 30 countries, mainly in South Asia and Central Africa. By the end of 2000, fewer than 3500 cases occurred in endemic areas throughout the world, and wild-type 2 poliovirus has not been detected since October 1999.⁹⁸⁸ At the close of 2001, the area of endemic poliomyelitis had been reduced to 10 countries, with fewer than 1000 cases reported.⁸²⁷

The global eradication program suffered a major setback in 2004 when OPV immunizations in northern Nigeria were suspended because of misinformation regarding vaccine safety.⁴⁸¹ After this suspension, epidemic disease caused by type 1 virus occurred throughout Nigeria and also spread directly or indirectly to 21 previously polio-free countries.¹⁶⁵ This epidemic, which had extensive spread, had a major negative impact on the Global Polio Eradication Initiative. During 2005, 1856 cases were reported globally, and 1000 of these cases occurred in countries with outbreaks caused by importation.

In 2011, there were four endemic countries (Afghanistan, India, Nigeria, and Pakistan).¹⁶⁹ In addition, reestablished transmission occurred in Angola, Chad, and the Democratic Republic of the Congo. In 2015 there were only 74 cases caused by wild polio virus found in Afghanistan

and Pakistan.⁸⁰⁰ As of May 2016 the only circulating wild-type virus is type 1. The last case caused by wild polio virus type 3 occurred in Nigeria in 2012.

Much attention is being paid to the end-game strategy for global polio eradication.^{250,306,305,612,793,892,1063,1130} Of particular concern for the future after world eradication of wild poliovirus strains is vaccine-associated paralytic poliomyelitis.^{250,297,298,614,615,799,1006} Other concerns are the long-term excretion of highly evolved vaccine-derived polioviruses in persons with primary immunodeficiencies and polio outbreaks associated with circulating vaccine-derived polioviruses in areas with low rates of OPV coverage. In 2014 to 2015 circulating vaccine-derived polio virus outbreaks occurred in five countries (Guinea, Laos, Madagascar, Myanmar, and Ukraine).^{298,800} In 2015 vaccine-derived poliovirus infections were also noted in the Democratic Republic of the Congo, Nigeria, Pakistan, and South Sudan. Ideally, an end-game strategy would transition to the use of IPV, but this strategy is not realistic in much of the developing world. As of June 2015, 90 WHO member states were using IPV.⁵⁴⁰ Twenty-two of these countries had introduced IPV after January 2013. Introduction of IPV in other member states is in progress. Currently in progress in countries using OPV is a switch from trivalent OPV to bivalent OPV (types 1 and 3).

Despite the substantial progress that has been made toward global eradication of polio, several challenges remain, including the following: (1) increasing vaccination levels in unvaccinated subpopulations; (2) preventing the reintroduction of wild poliovirus into polio-free areas by eliminating reservoirs in polio-endemic countries (particularly in the Indian subcontinent); (3) increasing the awareness of donor agencies and governments in industrialized countries of the substantial financial and humanitarian benefits of global eradication of polio, thus engendering support from unaffected countries beyond that already provided by organizations such as Rotary International; (4) encouraging all countries that remain polio endemic to make eradication of polio a high priority, including the implementation of NIDs and the initiation of acute flaccid paralysis surveillance; and (5) providing support to vaccination program managers for training to develop managerial skills for implementing and maintaining effective vaccination and surveillance programs in all countries.¹⁵⁸ The success of the Global Polio Eradication Initiative will depend on finding solutions to these financial, managerial, political, and technical challenges.

World events and new knowledge relating to reversion of poliovirus vaccine strains and recombination of poliovirus vaccine strains with nonpolio EVs led to the realization that decisions related to discontinuation of immunization after world eradication are exceedingly complex.^{613,827,1080,1182}

Rhinoviruses (RVs) are one of the most common etiologies of infections in people, causing 25% to 30% of all acute respiratory illnesses.^{104,116} RVs primarily lead to mild upper respiratory tract disease, but they also can cause bronchitis, sinusitis, and, on occasion, pneumonia in all age groups. These viruses are the most common precipitants of “infectious asthma” attacks, and they may also cause worsening of other lung diseases. Thus RVs constitute a significant health burden, particularly among children.

HISTORY

The first recognized human RV (serotype 1A) was isolated in monkey kidney cell culture by Pelon and associates²³² in 1954 from a recruit at Great Lakes Naval Training Center in Chicago during an outbreak of afebrile common colds in his training company. Independently, Price and colleagues²⁴³ reported the isolation of an antigenically identical virus from nurses and children with colds. In 1963, the RVs were so named because of their association with illnesses of the nasal passages.²⁹²

Before these actual virus isolations, evidence suggested that viruses cause the common cold. Despite indications that some coldlike illnesses could be complicated by bacterial infections,^{80,304} bacteria-free nasal filtrates from persons with apparent symptomatic respiratory tract infections clearly were able to initiate these illnesses. Kruse,¹⁸⁴ in 1914, first demonstrated transmission with apparently sterile filtrates, and his results were confirmed in the late 1920s in a series of experiments in humans and chimpanzees by Dochez and associates.⁸⁰ In the 1930s, workers from this latter laboratory reported growth of the agent in tissue culture and embryonated eggs, but their results were not confirmed.⁵ In the 1940s and 1950s, Andrewes and colleagues⁶ at the Common Cold Unit in Salisbury, England, and Dingle and the members of the US Armed Forces Commission on Acute Respiratory Diseases were able to transmit colds from person to person with apparently sterile filtrates.⁷⁹ Jackson and colleagues¹⁶¹ performed similar experiments in Chicago and also demonstrated immunity. In 1953, the Salisbury researchers reported isolation of an agent, DC, in serially passaged filtrates of tubed tissue cultures of human embryonic lungs; the virus was detected by its ability to produce colds in humans. Although these results could not be substantiated at the time, a virus was present; in 1968, the DC filtrates were found to contain RV serotype 9.^{5,62}

The next major advance in growing common cold viruses took place in the late 1950s in Salisbury. Tyrrell and Parsons²⁹³ inoculated human embryonic kidney cells with nasal filtrates and incubated the cultures under conditions simulating those of the nasal passages (e.g., 33°C, neutral pH, and in a roller drum for aeration). Six distinct types of RVs (serotypes 1B to 6) were isolated by observing cytopathic effects.²⁸¹ Shortly thereafter, Hamparian and coworkers^{136,179} isolated 18 RVs (serotypes 7 to 12 and 18 to 29) by using a semicontinuous diploid cell strain obtained by Hayflick and Moorhead¹⁴⁴ from human fetal lung cultures. The use of Hayflick’s cell lines greatly accelerated the isolation and characterization of “new” RVs, leading to the identification of 100 serotypes.¹³⁵

The use of molecular methods for the sensitive detection of RVs, beginning in the 1990s, further revolutionized the field by enhanced detection and typing of RVs in the clinical setting.^{187,197,233} In 2006, the detection of nonculturable RVs led to recognition of a wider diversity of recognized RVs associated with respiratory illness, including a new species (RV C).^{10,34,187} Improvements in detection by polymerase chain reaction (PCR) and sequencing techniques have resulted in the identification of diverse new genotypes.^{196,205} The application of molecular methods to viral diagnosis and improved methods of strain identification have led to a better understanding of the contribution of RVs to disease in

children, hospitalized patients, and immunocompromised patients in both research and clinical practice.

ORGANISM

RVs are members of the *Enterovirus* genus in the family *Picornaviridae*.¹⁸² Other members of the *Enterovirus* genus include polioviruses, Coxsackie viruses, and echoviruses. Like the other picornaviruses, the RVs are small (30 nm), nonenveloped (therefore resistant to lipid solvents such as ether and chloroform), and icosahedral (20-sided, hexagonal in cross section), with a genome consisting of single-stranded RNA (molecular weight, 2.5×10^6 Da) approximately 7200 nucleotides long.¹⁸² A picornavirus can be thought of as an RNA genome surrounded by a 20-sided protein coat (the capsid) (Fig. 167.1). The RNA alone is infectious and can serve as a messenger.

RVs previously were distinguished from classical enteroviruses by being rendered noninfectious at an acidity lower than pH 5 and by their higher buoyant density in cesium chloride. RVs are subdivided based on various virus characteristics as follows: (1) into three species (RV A, RV B, and RV C) based on genomic sequence analysis; (2) into three groups based on receptor use (see later); (3) into two groups based on susceptibility to capsid-binding antiviral agents (groups 1 and 2); (4) into more than 100 serotypes, as described earlier; and (5) into more than 150 genotypes.^{164,205} PCR assays or other molecular analyses are typically used to distinguish other enterovirus species from RVs.^{164,196}

The genomes of the original 100 culturable serotypes and multiple nonculturable RV genotypes have been sequenced completely.²²⁹ Classification is now based on phylogenetic analyses. Species and genotype can be assigned by analysis of the *VP1* or *VP4* genes. Within an RV species, there is no more than 12% to 13% nucleotide sequence divergence of the *VP1* gene within a genotype. The recognition of new genotypes requires the analysis of the complete *VP1* sequence.²⁰⁵ With this classification system, RV genotypes are now identified by species and genotype; thus viruses belonging to the RV A species and genotype 100 are designated as A100.¹¹⁵

A virus previously classified as RV serotype 87 has greater sequence homology to the *Enterovirus D* species (EV-D68 and EV-D70) than to other RVs, leading to its reclassification into the *Enterovirus D* species.³⁰

Structure of the Virion

The virion is composed of 60 copies of each of four structural proteins: VP1, VP2, VP3, and VP4. Knowledge of the structure of the RVs is based on the determination of the capsid structures in atomic detail for five types, A01, A02, A16, B03, and B14.^{11,180,255,256,298,316} The thin (5-nm) protein capsid has an undulating exterior marked by 12 vertices (the icosahedral fivefold axis) equally spaced over the surface. Surrounding these vertices is a steep (2.5-nm deep), narrow canyon. VP1, VP2, and VP3 are exposed on the surface of the virion, whereas VP4 is buried within the capsid.

A pocket of unknown function whose walls are lined by 17 amino acids that vary with each RV type has been found at the base of the canyon.⁷ Various organic molecules have been determined to bind in this pocket; when these molecules are bound, either the virus is prevented from uncoating (necessary to release viral RNA for its translation to viral protein) or the cell receptor is prevented from docking in the canyon.^{105,236,258} Numerous drugs made by several different drug companies in the United States, Europe, and Japan have been developed to exploit the antipicornavirus potentialities of this pocket, and the sensitivity of the RVs to these drugs has been used as an additional means of classifying the RV A and RV B genotypes (into inhibitor groups 1 and 2).^{8,7,115} One group

of these drugs, the WIN compounds synthesized by Sterling-Winthrop, has had wide scientific exposure; however, clinical trials have been discouraging.^{284,286} One disadvantage of these compounds is that the various RV serotypes vary widely in sensitivity to these organic molecules.⁷ Another problem has been failure to attain effective concentrations of drug at the site of infection.

Virus Life Cycle

The first step in the virus life cycle is binding to its cellular receptor. There are only two different receptor binding sites for the serotypes that belong to the RV A and B genotypes: 89 serotypes bind to intercellular adhesion molecule-1 (ICAM-1, the major receptor group), and 11 other serotypes (all from the RV A genotype) bind to members of the low-density lipoprotein receptor family (LDL-R, the minor receptor group).^{1,115,122} The receptor(s) of RV C viruses have not been identified but are distinct from the two currently recognized receptors for RV A and RV B strains.³²

ICAM-1 binds to the base of the canyon of RVs in the major receptor group.^{257,295} Virus-neutralizing antibody prevents virus attachment to cells by adhering to serospecific sites and blocking the cell receptor from access to its binding site at the canyon base. These antibody sites may directly overlap ICAM-1-binding sites, or they may be separate from the ICAM-1-binding sites but at a point sufficiently close to allow the binding site to be blocked by steric hindrance.⁵⁰ Binding of the major receptor group RVs to ICAM-1 leads to destabilization of the virus capsid and uncoating of the viral RNA.¹²³ Some major group receptor viruses are also able to use heparan sulfate proteoglycans as an alternative receptor, either directly or following adaptation.¹⁰⁸

The LDL-R family binds to a different site for the minor receptor group of RVs than that recognized by ICAM-1. The binding site for these RVs is the small, star-shaped dome above the canyon on the icosahedral fivefold axis. Multiple receptors are rapidly and sequentially bound.²⁵¹ Attachment of minor receptor group viruses to LDL-R does not lead to virus uncoating, in contrast to what is seen with binding of major receptor group RVs to ICAM-1. Instead, internalization into acidic endosomal compartments is required for uncoating of minor receptor group RVs.¹⁵⁰

Replication of the RVs is similar to that of the enteroviruses.²⁴⁹ After attachment to the cellular receptor and endocytosis of the virus, RNA is released into the cytoplasm. Genomic viral RNA functions as messenger RNA and attaches to ribosomes, which stimulates its translation by host enzymes into a single long polypeptide. This polypeptide is cleaved by viral proteases to yield viral RNA polymerase, capsid proteins, proteases, and proteins to halt the synthesis of host proteins and other

products. Under laboratory conditions, infectious virus first is formed after approximately 2 hours and reaches a maximum of approximately 1000 infectious particles per cell at approximately 7 hours. Infectious virus, however, comprises a minority of the viruslike particles formed; only approximately one in 200 is a complete virus capable of replicating in cell culture. All viral replication occurs in the cytoplasm, and viruses are released by cell lysis in a process involving apoptosis.^{71,249}

Host Range

Animals

RVs have been isolated from natural infections in only chimpanzees and humans. Chimpanzee infections are subclinical. A natural, subclinical outbreak of RV-31 in chimpanzees was reported in a primate center.^{74,73}

Many attempts have been made to infect a wide variety of animals with RVs. In addition to the chimpanzee, the gibbon has been susceptible, although not reliably so.⁷⁴ Mice do not naturally express ICAM-1, the major receptor, and are not infected by these viruses. The block can be overcome by engineering mouse cells to express ICAM-1, a finding that led to the development of a transgenic mouse model for RV infection.^{26,27,139} Mice also can be infected by RVs that express the minor receptor.^{27,314} Mutations in viral nonstructural proteins can improve the replication efficiency of mouse-adapted RVs in both major and minor receptor groups.^{139,314} Equine and bovine “rhinoviruses” have been described, but these viruses belong to different picornavirus genera.

Cell and Tissue Cultures

The spectrum of tissue culture cells infected by RVs also is narrow.^{64,188} For initial isolation, human embryonic diploid cells generally are used for isolation of RV A and B strains (Fig. 167.2), although for some RV types, an especially sensitive strain⁶¹ of a continuous cell line, HeLa, serves as well or better.^{64,188} RV C strains are not cultivable in traditional cell lines. However, these viruses can be propagated in primary respiratory epithelium cultures and in three-dimensional human airway cultures.^{138,279}

Antigenic Properties

A prominent characteristic of RV is its great antigenic diversity; more than 100 cultivable serotypes exist.¹³⁵ Genetic analyses suggest that close to 50 additional serotypes may exist among RV C strains.^{206,267} The number of additional serotypes of cultivable strains may be limited.^{104,135,218} There are conserved domains in the capsid to which cross-reactive cellular responses and heterosubtypic neutralizing antibody responses can be generated; these have been proposed as a potential target for future vaccine development efforts.¹²⁰ Certain serotypes cross-react, but there is little evidence to indicate that this cross-reaction can be exploited for vaccination.^{63,102,215}

RVs often are poor antigens based on the immune responses observed after infection. Significant (fourfold or greater) increases in serum antibody may not develop in as many as 50% of patients from whom RVs are isolated, and the levels attained often are low.¹⁰²⁻¹⁰⁴

RVs may be undergoing continuous antigenic change.²¹⁵ Genetic analysis of the capsid genes of RV C strains found high substitution rates.¹⁸⁵ Another mechanism that may lead to the emergence of new strains is recombination. The sequencing of complete viral genomes has identified a number of probable recombination events between different virus serotypes, especially among RV A and C strains.³⁰⁰ The recombinants then diverged further from the parental strains and became new serotypes.²²⁹ Antigenic variation within serotypes RV-22 and RV-51 has been substantial enough to interfere with their typing.^{262,275}

EPIDEMIOLOGY

RVs cause infection with a worldwide distribution, and large epidemiologic studies have consistently identified RVs as the most common cause of viral respiratory disease. For example, two population-based studies in Roehampton, England¹⁵⁴ and Tecumseh, Michigan²¹⁹ found RVs more frequently than other respiratory viruses, with RVs causing 26.3% and 38.1%, respectively, of all respiratory illnesses. More recent studies of acute respiratory illness in children also identified RVs most commonly.^{39,202} Infection is more common in children than in adults. The annual incidence in children is approximately one infection per

FIG. 167.2 Rhinovirus type 16 infection. (A) Normal human diploid (fetal tonsil) cell sheet. (B) Cell sheet infected for 2 days with rhinovirus type 16. The rounded and misshapen cells are characteristic. (Courtesy Dr. David M. Warshauer, University of Wisconsin, Madison, WI.)

year, although one study reported an incidence as high as six infections per year.³¹⁰

Seasonal Distribution

RV causes infections year round, although there are seasonal peaks of occurrence.²¹⁷ During the usual September through May “cold season,” RV infections often are predominant at both ends, early fall and middle to late spring (Fig. 167.3). They also are important causes of summer colds. In the Southern Hemisphere, a similar seasonal pattern occurs, but during opposing months.¹⁷⁰

Cycling and Circulation of Individual Rhinovirus Types

Several RV serotypes usually circulate simultaneously within a community,¹³⁷ frequently coincident with other respiratory viruses.^{72,154,219} For example, in a study of 24 neighboring families in Madison, Wisconsin (Eagle Heights Village), 14 different RV types, in addition to several nontypeable RVs, were found during the two academic years 1963 to 1965. Only a single type (RV-15) was found both years. The other common respiratory viruses also were present. In virus surveillance studies performed in families in Seattle and Tecumseh, a few “common” serotypes were found to be more prevalent in a given respiratory season and to be identified in subsequent respiratory seasons.^{104,218} However, most individual RV types do not repeat within a population from year to year.

Although several RV types usually circulate concurrently, all types present are not equal in prevalence. In a Chicago nursery school study,²⁸ 14 different serotypes were isolated during the academic year 1962 to 1963, but 10 of the serotypes did not spread at all. Only 3 types disseminated widely, and they infected more than 40% of the children. Similarly, in the 1963 to 1965 Eagle Heights Village study, 14 RV types were isolated, but only 3 types (RV-43, RV-51, and RV-55) were “spreaders.” Similar patterns of serologic prevalence were reported from laboratories in Tecumseh,²¹⁹ New York City, Seattle,^{103,104} and Charlottesville, Virginia.¹⁴⁸

Predominating Rhinovirus Types

Although the pattern of predominating RV types within a circumscribed population and a defined time frame seem to be well established, a predominance of serotypes over large geographic areas or over many

years does not seem to occur. This phenomenon was studied exhaustively in widely separated locations and over many years: the Gulf South from 1962 to 1970, Tecumseh from 1966 to 1971 and from 1976 to 1981, and Seattle from 1965 to 1969 and from 1975 to 1979.^{103,104,215,218,220} Although “common types” (usually the isolation of at least five to eight strains of a serotype during the period studied) occurred during each period and at each place, different types were “common” findings in different places and times. For example, Monto and colleagues,^{218,220} during two 6-year study periods in Tecumseh, obtained 475 RV isolates covering 70 serotypes (of a possible 89 at that time), but only RV-1B, RV-10, RV-28, and RV-58 were isolated in both periods. However, these viruses were not particularly common because only 16, 22, 15, and 18 isolates, respectively, of these four types were found during the 12 years. In the neighboring state of Wisconsin from 1963 to 1965,⁷² the common types were RV-43, RV-51, and RV-55, which were completely different from those in Michigan. Finally, the late John Fox sifted data from family populations surveyed by him and others in New York City, Seattle, and Tecumseh.^{103,104} He found only 4 common serotypes (RV-1B, RV-12, RV-15, and RV-38) from among 802 isolates. Dominant RV serotypes often appear to occur locally over relatively short periods but do not extend for decades or over the nation, at least in the United States.

More recent studies using molecular assays indicate that the number of circulating strains in a given geographic area is even greater than previously appreciated using only cell culture methods. Investigators in the Netherlands identified 27 different genotypes of RV infection among a cohort of 18 healthy children 7 years of age and younger sampled at least every 2 weeks over a 6-month period.²⁹⁷ Mackay and colleagues¹⁹⁷ identified 74 distinct RV genotypes from all 3 RV species circulating over a 1-year period in 234 children in Melbourne, Australia. Thus the diversity of RVs present in a community is greater than previously recognized.

Median Human Infectious Dose for Rhinovirus

As documented in RV challenge experiments with laboratory-grown virus administered by nose drops or aerosol, less than one median tissue culture infective dose (TCID₅₀) can initiate infection.^{68,82} Much more (2000 times) is required when placed on the tongue or dried just outside the anterior nares (10,000 times).⁶⁸ How accurately these conditions approach the natural state is not known.

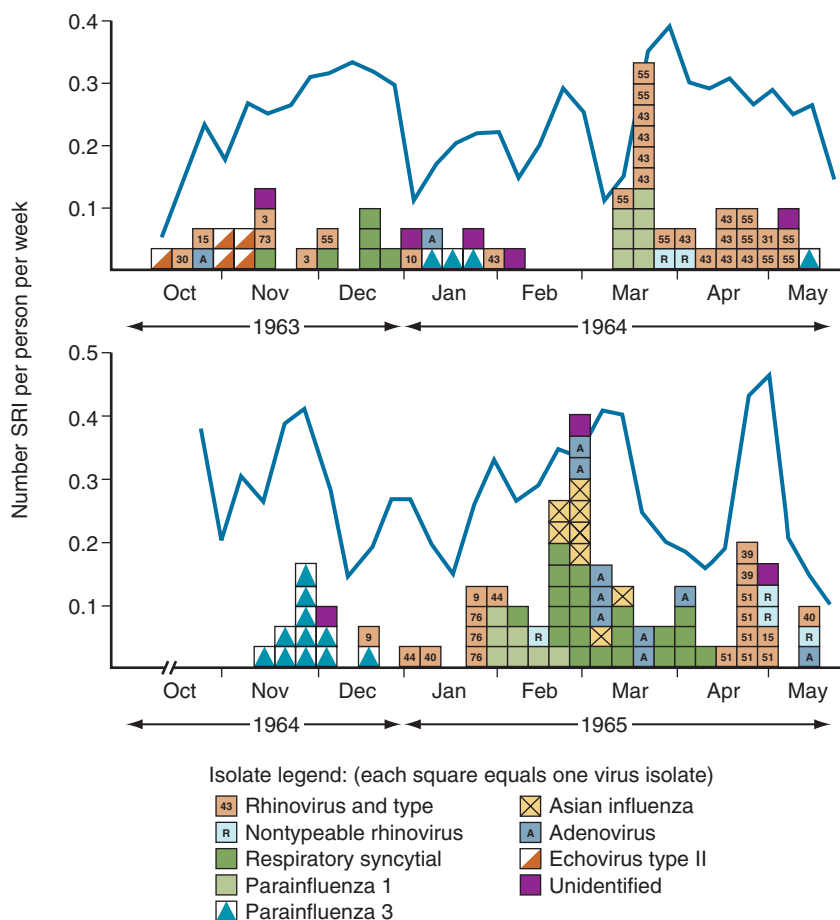

FIG. 167.3 Rhinoviruses and other respiratory viruses associated with symptomatic respiratory infection (SRI). This study included three neighboring apartment buildings in Eagle Heights, a University of Wisconsin housing village in Madison, Wisconsin (24–26 families, ≈100 persons), from 1963 to 1965.

PERSON-TO-PERSON TRANSMISSION

Epidemiologic Observations

Individual RV serotypes often disseminate with surprising difficulty, as noted in studies of Eagle Heights Village,⁷² a Madison, Wisconsin, elementary school, and a Chicago nursery school.²⁸ At least within family populations, the most common finding was that a specific RV serotype did not spread from the index case. Hendley and associates,¹⁴⁸ in a study of 19 families in Charlottesville, found that RVs from 10 of 22 index cases did not spread at all, and dissemination to at least one other person occurred in only seven families. In only four of the 19 families did further sequential spread occur. Fox and associates,^{103,104} in a surveillance of more than 200 Seattle families, found intrafamily secondary attack rates in susceptible individuals (no homotypic antibody) to be 44% from 1965 to 1969 and 28% from 1975 to 1979. In both periods, children younger than 5 years had the highest secondary attack rates of 60% and 30%, respectively. Monto and Johnson^{216,221} reported similar findings in 48 Panamanian families: with five RV isolates used as antigens, the secondary attack rate varied from 10.5% to 56%.

In Madison, interfamily and intrafamily dissemination of the 3 “spreading” RV types, RV-43, RV-51, and RV-55, was examined in the 24 to 26 neighboring families living in fourplex apartments in Eagle Heights Village (Fig. 167.4).⁷² These 3 serotypes were the only ones of 14 to spread beyond the index family. RV-51 attacked 23% of susceptible individuals, and many close contacts remained uninfected. RV-43 infected 34% of susceptible individuals; in one building, only the families in a single-end fourplex became infected. Conversely, RV-55 caused a mini-epidemic in two buildings. RV dissemination seemed to focus on the fourplex, probably because in the winter months the children played in the hallways and stairs connecting the apartments. Nonetheless, even the spreading RVs left many susceptible individuals in untouched families.

Determination of the reason for such erratic spreading patterns can be sought in well-controlled chain-of-infection experiments with human

volunteers. RV transmission experiments from several laboratories are described next.

Person-to-Person Transmission to Human Volunteers

Early Experiments With Rhinovirus Colds

Early experiments with different RV serotypes showed that person-to-person transmission occurred infrequently. Couch and colleagues⁶⁷ attained no transmission after housing 15 donors (persons infected intranasally with laboratory-grown RV-15) with 12 antibody-negative recipients for 26 days. At approximately the same time, the Madison laboratory performed transmission trials with RV-55 and RV-16 in a series of experiments ranging in duration from a 1- to 1.5-minute kiss to a 3-day weekend in a dormitory room. In 26 donors and 33 recipients, only two transmissions occurred, one from a 1.5-minute kiss and the other from a weekend in a dormitory.⁶⁸ Only when young married student couples were used was a substantial rate attained; nine of 24 spouses infected their mates, for a transmission rate of 38%.⁶⁹

Characteristics of a “Good” Rhinovirus Transmitter

In the experiments with married couples, “successful” donors shed enough virus to contaminate their environment, exhibited signs and symptoms of a moderate to severe cold, and spent many hours at home with their spouses.⁶⁹ As an example of the effect of high virus shedding, intracouple transmission rates were 71% for donors with nasopharyngeal RV titers of 5000 to more than 80,000 TCID₅₀, 33% for those with 1000 to 5000 TCID₅₀, and only 18% for those with less than 1000 TCID₅₀ ($P = .025$). Illustrative of both shedding and production of sufficient nasal secretions was contamination of the hands with RV: donors whose hands were assayed for virus and who transmitted infections to their spouses all had RV on their hands, whereas none of the nontransmitters did ($P = .03$). The amount of time spent together seemed important in transmission, although many infected spouses who spent hours of direct contact with their partners did not transmit the infection.

Some Early Conclusions

The preceding epidemiologic human volunteer studies suggest that attending a concert with persons who have even obvious signs of colds is unlikely to result in infection. Conversely, students who spend day after day in classrooms may have a higher chance of acquiring infection. In addition, a relatively short stay (a few hours) among friends or relatives with RV-caused colds is not likely to cause infection, even with brief embracing.

Route-of-Transmission Experiments

Because RVs often seem to spread with relative difficulty under many normal circumstances, the route of transmission becomes important because controlling respiratory virus transmission in habitats such as schoolrooms and families may be feasible by blocking transmission routes. Since the early 1970s, human volunteer experimental infection models have been used to explore RV transmission routes. These studies were performed primarily at the University of Virginia, England's Common Cold Unit, and the University of Wisconsin.

Gwaltney and Hendley¹²⁹ at the University of Virginia focused on the dissemination of RV colds by direct or indirect hand contact. Interest in this approach had been provoked by the inadvertent transmission of RVs from infected to noninfected persons through the vehicle of an ethanol-sterilized nasal speculum. Subsequently, the plausibility of direct hand transmission of RVs was supported by the observation that nose picking and eye rubbing were common among Department of Medicine Grand Rounds participants and Sunday school attendees,¹⁴⁹ following previous documentation of infection through conjunctival swabs.⁴⁰ These investigators then showed that RV-39 retained infectivity for several hours on various surfaces and could be found on the hands of persons infected with RV-39. In another study, infectious RV was isolated from the fingertips of 22% of persons who touched objects that had been contaminated with nasal mucus of adults with natural colds one hour earlier.³¹¹ These experiments suggest that transmission of RV could occur through self-inoculation by environmentally contaminated hands and demonstrated RV-39 self-inoculation from an environmental source in human volunteers.¹⁴⁹

The University of Virginia team in Charlottesville subsequently conducted a series of three experiments that identified direct inoculation as a route of RV transmission.¹³¹ In two of the experiments, groups of recipients were exposed to aerosols generated by donors infected with an untypeable RV strain, HH, and the exposures occurred in separate closed rooms for large-particle (12 recipients) or small-particle (10 recipients) aerosols produced by donors during periods of 45 minutes

(large particles) or 3 days (small particles). One of the large-particle aerosol recipients was infected, whereas no one exposed to small-particle aerosols was. These essentially negative transmission rates by aerosol exposure were not surprising.¹²⁹ Previously, Couch⁶⁵ had been unsuccessful in transmitting infection through the airborne route over a period of 26 days, and the Madison laboratory attained only a single RV transmission among 11 recipients after 3 days' exposure in a dormitory.⁶⁸ The third group of Charlottesville recipients was exposed to RV by inoculating themselves with the donor's nasal mucus. The donors blew their noses into their hands. The recipients then stroked the donors' contaminated hands for 10 seconds and then inoculated themselves by deliberately placing their fingers, two or three times, on their nasal and conjunctival mucosa on 3 successive days. Eleven of the 15 hand-contact recipients (73%) were infected with the donors' RV. The authors concluded that transmission by the hand-contact/self-inoculation route was much more efficient than the aerosol route and “may be an important natural route of RV transmission.”¹³¹

One deficiency of this experiment was that donors and recipients shared the same air space over a measured, often brief, period during which fresh nasal mucus was transferred from the donor to the recipient. Nonetheless, Gwaltney did achieve a high rate of RV transmission with nasal secretions, something that had not been accomplished readily in more “natural” experiments.⁶⁸ Also in support of hand transmission was the observation in the aforementioned married-couple experiments that the ability to transmit RV was correlated significantly with the presence of the virus on the donors' hands.⁶⁹ As a result of this evidence, hand-to-hand or fomite transmission became the accepted route for RV contagion.^{44,65} In later experiments, the Charlottesville group demonstrated approximately 50% transmission through fomites by using the same hand-contact/self-inoculation method with either a coffee-cup handle or a plastic tile interposed between donors' and recipients' hands.¹³⁰

At England's Common Cold Unit, Reed²⁵² investigated the likelihood of natural hand-contact transmission among residents (roommates) of several housing units, 38 of whom had been infected with RV-2. Reed²⁵² found that 16 of the donors had RV on their fingers, but none of the virus was transmitted to the fingers of their 18 roommates, even though virus could be recovered from some (6 of 40) objects recently handled by RV-2-infected donors. Reed also found that none of 29 virus transfers from virus dried on the fingers could pass through a fomite to a recipient; the conclusion was that “spread of colds is unlikely to occur via objects contaminated by the hands of the virus shedder...”

Laboratory workers at the University of Wisconsin continued their attempts to devise a natural transmission model. Although the results

of the transmission experiment with married couples were illuminating, the system itself had one great deficiency as an experimental model: the participants could not be observed during their interaction periods.⁶⁹ Ultimately, the scheme for such a system was suggested by two virologic-epidemiologic events in Antarctica, one from the summer seasons of 1975 to 1980 in which Dick and associates studied respiratory virus dissemination in an isolated Antarctic population, and the other from a human volunteer experiment conducted in an Antarctic field party by England's Common Cold Unit.³⁰³ Both experiences suggested that high natural transmission rates after just a few days of exposure could be achieved only in an environment with a high donor-to-recipient ratio and population density. Accordingly, a model was devised in which donors (with the qualities of a "good" transmitter as described earlier) and recipients interacted during waking hours by playing cards and board and video games and engaging in communal studying. During the night, donors and recipients bunked together in the same or an adjoining room. With such an arrangement, graduate student monitors recorded activities and all clinical signs 24 hours a day. With eight donors and 12 to 16 recipients, a 50% recipient attack rate usually was attained over a 12-hour period and a 100% rate over the course of a week.^{78,209} Informally, this model, a fully observed monotypic RV mini-epidemic, was named "Antarctic Hut," from its origins.¹⁴⁷

Route-of-Transmission "Blocking" Experiments

With the use of the Antarctic Hut model, a series of four RV-16 route-of-transmission blocking experiments was conducted to determine whether the virus was spread by hand contact, aerosol, or both.⁷⁸ The first three experiments lasted 12 hours, with eight donors and 12 recipients; the donor-recipient interaction was through playing variants of stud and draw poker. This interaction mode facilitated both aerosol and fomite/hand-contact transmission. Half the recipients were blocked completely from any hand contact/self-inoculation by wearing arm restraints. Little transmission resulted from hand or fomite contact because the RV-16 infection rate in the restrained recipients was only slightly lower than in the unrestrained recipients, 56% versus 67%, an insignificant reduction ($P = .494$).

The fourth experiment, involving aerosol blocking, was begun immediately after the third. The poker game continued in the original room with eight donors alone, and all the equipment from the third experiment, including the cards (which literally were gummy from the previous 12-hour game), poker chips, pencils, and so forth, was moved to an identical room across the hall. The continuing eight-donor poker game in the room used for the third experiment was refurnished with poker implements. Subsequently, 12 new recipients entered the second room, began playing poker with the now heavily used cards and other paraphernalia, and made exaggerated hand-to-nose self-inoculation movements. Aerosol transmission was blocked effectively by the two brick walls between the rooms. Once each hour, the cards, poker chips, and other portables were exchanged between the donor and recipient rooms to maintain a freshly contaminated supply of fomites in the recipient room. The result was extremely surprising; not one of the 12 "fomite recipients" caught RV-16. Judging from the results of these Antarctic Hut experiments in which fomite/hand-contact and aerosol transmission were blocked alternately, aerosol transmission seemed

the predominant route, at least for RV-16 among student poker players at the University of Wisconsin. A few months after the 1987 publication of these results, an editorial appeared in *The Lancet* titled "Splints Don't Stop Colds: Surprising!"^{78,272} It concluded that "...it looks as though coughs and sneezes *do* spread these diseases more than sticky fingers."

Subsequently, a set of experiments was conducted to determine how RV-16 had disappeared along the five-step fomite transmission chain from nose to hand to fomite to hand to nose.¹⁶⁹ The same results that Reed²⁵² had observed previously were again noted. The virus seemed to disappear precipitously at each step in the chain; 10⁶ TCID₅₀ of RV-16 in the donor's nose was reduced to 0 to 64 TCID₅₀ on the card-playing implements, and then the virus nearly disappeared on reaching the recipients' hands.

Additional studies examined other methods to interrupt transmission. The University of Virginia team performed a blocking experiment in the field in which mothers attempted to prevent hand contact/self-inoculation by dipping their fingers in iodine. The results of this 1979 to 1982 study were reported as part of a general review.¹⁴⁷ The illness rate during the 4 years was 40% lower in the mothers with iodinated fingers than in the placebo mothers ($P = .047$). However, the authors noted the difficulty of conducting and interpreting these investigations.¹⁴⁷ In another set of experimental human infection studies, the application of organic acids present in hand cleansers (e.g., salicylic acid, pyroglutamic acid) to the hands of volunteers decreased the likelihood of RV infection when volunteers subsequently touched their nasal or conjunctival mucosa 10 minutes after RV had been placed on their hands.²⁸⁷

The Madison group also examined transmission interruption methods to prevent spread from person to person. As part of an investigation of the epidemiology of respiratory viruses in an isolated (≈200 persons) Antarctic population at McMurdo Station in 1979, use of an iodinated facial tissue was successful in interrupting transmission.⁷⁵ Three days after all personnel began copious use of these tissues, the incidence of respiratory illness dropped rapidly and significantly ($P < .01$); in fact, respiratory illness nearly disappeared from the base.⁷⁷ Although this effect was striking, the trial could be controlled only historically. However, the apparent success was sufficient to interest the Kimberly-Clark Corporation in applying virucidal facial tissue technology to interrupt RV-16 transmission in the Antarctic Hut model. The Kimberly-Clark Corporation soon made available a nontoxic, highly virucidal facial tissue. The tissues completely stopped transmission of RV-16, in comparison to transmission rates of 42% and 75% in control recipients using ordinary cotton handkerchiefs ($P < .001$) (Table 167.1).⁷⁶ The corporation test-marketed these tissues under the brand name "Avert," but their sales were lower than expected. Subsequently, two field trials of Avert in families reduced viral transmission of 5% to 39%, respectively.^{96,193} These results were disappointing but not unexpected. Changing established habits of personal nasal sanitation was not easy in the highly supervised, well-motivated adults in Antarctica; it may be impossible in unsupervised children.

Despite all the experimental studies to identify the principal route of virus transmission, no single route appears to be predominant. What is clear from these studies is that RV illnesses may be transmitted by both the hand-contact and aerosol routes.

TABLE 167.1 Apparent Complete Interruption by Virucidal Tissues of Rhinovirus Type 16 Transmission^a

Study Group	Cotton Handkerchiefs Experiment A	Virucidal Tissues Experiment B	Virucidal Tissues Experiment C	Cotton Handkerchiefs Experiment D
Recipients who "caught" RV-16 colds/total (%) ^b	5/12 (42)	0/12	0/12	9/12 (75)

^aIn each of four experiments, eight volunteers with RV-16 colds played poker for 12 hours with 12 other volunteers (without RV-16 antibody) and for nasal sanitation used either ordinary cotton handkerchiefs (experiments A and D) or virucidal tissues (experiments B and C). Three-ply Kleenex tissues were treated, per 100 g, with 9.1 g citric acid, 4.5 g malic acid, and 1.8 g sodium lauryl sulfate. Cotton or paper handkerchiefs were used to clear nasal passages, to smother coughs and sneezes, and to wipe surfaces. Virucidal tissues were used carefully and copiously.

^bDiagnosed by at least one isolation of RV-16 or a fourfold rise in antibody to RV-16 in the convalescent serum sample, or both.

RV-16, Rhinovirus type 16.

PATHOGENESIS AND HOST FACTORS

General Course of Infection

Infection usually occurs through the respiratory route, although infection by the conjunctival route has been demonstrated.^{40,149} When the virus is given intranasally by pipette, only one TCID₅₀ is needed to initiate infection.^{68,82} The incubation period for a cold normally is 2 to 3 days, but a period of up to 7 days has been reported.^{83,148} Ciliary dysfunction can predispose to respiratory tract infection.^{31,43} RVs replicate well in both the upper and lower respiratory tracts.

RVs may be shed in large amounts (1000 to 1 million infectious particles per milliliter of nasal washing) during the first 2 to 3 days of a cold and may be produced for 2 to 3 weeks thereafter.^{78,82,83,209} However, the effect on cells of the nasopharyngeal cavity seems benign despite much local reaction to the virus, which results in the usual signs and symptoms of a cold. Systematic studies of RV-inoculated human volunteers at the University of Virginia demonstrated that damage to the respiratory epithelium was slight, although a few sloughed ciliated epithelial cells did contain RV antigen.^{288,307} RV was recovered only at focal sites in the nose and nasopharynx at the time of maximal symptoms, and in situ hybridization studies demonstrated evidence of RV infection in only a minority of epithelial cells.^{16,24,309} Using primary monolayer cultures of ciliated and nonciliated epithelial cells, Winther and associates³⁰⁸ demonstrated that RV, coronavirus, influenza A virus, and adenovirus all grew well in these cell cultures; however, RV and coronavirus produced no discernible cytopathic effect compared with the widespread destruction of the cell monolayer by influenza virus and adenovirus by 96 hours.

Innate Immune Response

Innate immunity is the initial host response to infection with RVs. Toll-like receptor 3 (TLR3) is activated during virus replication, is upregulated during RV infection, and is associated with decreased viral replication.¹⁵¹ Signaling occurs through both retinoic acid inducible gene I (RIG-I) and melanoma differentiation associate gene 5 (MDA-5), and inhibition of these molecules leads to increased viral replication.²⁶⁹ One mechanism of inhibition of intracellular signaling developed by the virus is cleavage of the signaling molecules (e.g., RIG-I, interferon- β [IFN- β] promoter stimulator 1 [IPS-1]) by the viral protease.^{25,89} Toll-like receptor activation leads to the production of type 1 IFNs, which is likely the mechanism by which viral replication is inhibited. Impaired induction of IFN- β leads to increased viral replication and is a defect that has been identified in the respiratory epithelium of asthmatic patients.^{231,302} Numerous other components of innate immunity are also induced by RV infection, including β -defensins, nitric oxide, and a variety of proinflammatory cytokines and chemokines (e.g., interleukin [IL]-1, IL-6, IL-8, RANTES [regulated on activation, normal T cell expressed and secreted]).^{247,250}

Because RVs seem to cause only mild pathologic changes in cells of the respiratory tract, attention has focused on various immunologic or inflammatory substances as possible causes of symptomatic illness.²⁸³ Researchers have long known that peripheral blood neutrophils increase in the first 2 to 3 days of illness in RV-infected volunteers.^{45,283} Phagocytes (neutrophils and monocytes) also have been demonstrated in large numbers in the nasal secretions of RV-infected symptomatic human volunteers.¹⁹² Although the microbe-killing ability of phagocytes is well known, these cells in themselves also can cause cold symptoms through the release of various toxic products, such as superoxide and hydrogen peroxide, during the respiratory burst.²⁸⁰ In fact, increasing numbers of leukocytes in the peripheral blood correlate with increased symptoms and in infected human volunteers who are not ill the white blood cell count does not increase.²⁸³ An association has been noted between the nasal levels of two proinflammatory mediators involved in granulocyte regulation, granulocyte colony-stimulating factor, and IL-8, and blood and nasal neutrophilia have been identified.^{117,228} Nasal IL-8 levels also correlate with the severity of clinical symptoms.^{124,290}

Increased nasal levels of other inflammatory mediators (e.g., IL-1 β , IL-6, RANTES, kinins) have been associated with more severe clinical symptoms.^{224,228,244,245,318} Furthermore, topical nasal administration of IL-6 or bradykinin leads to development of some of the symptoms of the common cold.^{110,246} At least some of these inflammatory responses appear to depend on an activation pathway regulated by nuclear factor κ B

(NF- κ B).^{317,318} There may also be differential levels of cytokine induction by different RV species, with RV B strains inducing lower levels of chemokines and cytokines than RV A and RV C strains.²²⁵ Resolution of clinical symptoms may be caused by the elaboration of inhibitors of inflammation, such as IL-1 receptor antagonist.³¹⁵ Transcriptome analysis of children with symptomatic RV infection has also shown upregulation of innate immune response genes, although there is little change in the expression of these genes in children with asymptomatic infection.¹⁴⁵ These inflammatory mediators may serve as a target for the development of drugs to relieve the symptoms of RV infection, although the use of a specific kinin inhibitor did not lead to clinical improvement.^{127,153}

Immunity Associated With Serum Antibody

Serum antibody to the various RV types develops with age (presumably from repeated infections); and by adulthood, antibody may be detected against approximately 50% of RV types tested.¹²⁸ The presence of serum antibody correlates positively with immunity, and resistance to infection and the degree of disease expression are related to the amount of antibody present.^{3,2,38} As examples, in the Eagle Heights Village families, 21 of 75 persons (28%) without antibody were infected with either RV-43 or RV-55, whereas only five of 35 (14%) with homologous antibody to either of these agents were infected.⁷² No one was infected who had homologous serum antibody levels above 1:16. Similar results were observed in the Charlottesville and Seattle families.^{103,104,148} However, large doses can overwhelm antibody. At the clinical center of the National Institute of Allergy and Infectious Diseases, where human volunteers were used, 1000 TCID₅₀ was found to infect persons with serum antibody titers up to 1:256.⁴⁶ Judging from the paucity of reports of natural infections in persons with serum antibody titers greater than 1:16, virus inocula in naturally contracted cases must be low.

Immunity Associated With Antibody in Nasal Secretions

Researchers at the National Institutes of Health found that the presence of antibody in nasal secretion is associated with protection from homologous RV infection and disease.⁴⁷ They found that intranasal administration of inactivated RV vaccine produced both serum and nasal antibody, whereas two intramuscular injections of this vaccine produced little, if any, nasal antibody.²³⁵ When the volunteers given the vaccine intranasally were challenged with approximately 100 TCID₅₀ of homologous RV, they were protected significantly against both clinical illness and infection, whereas those administered the same vaccine intramuscularly remained susceptible.²³⁵

Conversely, when the same vaccine preparation was administered subcutaneously in three injections, nasal antibody responses were observed in 21 of 46 (45%) volunteers.^{84,79} Challenge of these volunteers with 3 TCID₅₀ of virus produced significantly less virus shedding and reduced duration and severity of illness than were observed in unimmunized controls who had no RV-specific antibody. Possibly, this lower infectious dose more closely approximates a natural situation. This study also showed that protection against infection with the low virus challenge correlated with the magnitude of serum antibody and not with the presence of secretory antibody. The relative roles of serum and secretory antibody in RV infections are still unsettled.

Antibody Appearance Over the Course of Infection

There is a general pattern of the development of humoral (secretory and serum) antibody based on human studies.^{38,86} Approximately 24 hours after infection, a sharp increase in nasal immunoglobulin (IgA) secretion occurs. At the time symptoms appear (approximately 48 hours after infection), rhinorrhea begins, and the transudate is composed of significant amounts of IgG. After approximately 1 week and after the actual episode of illness, virus-specific antibody, predominantly IgA, appears in the nasal passages, tears, and the parotid saliva. Serum antibody (usually IgG but occasionally IgM) also begins to be formed at 1 week and rises to peak levels at 1 month. Both serum and secretory antibodies appear sooner and rise more rapidly in persons with detectable neutralizing antibody in their preinfection serum specimens. Antibody has been detected in nasal secretions and serum approximately 1 year after infection and, judging from the high proportion of the adult population with antibody to many RV serotypes, probably lasts much longer.^{36,128}

Cell-Mediated Immunity

Substantial evidence indicates that neutrophils increase both in the peripheral blood and in the nasopharynx during the first few days of an RV cold.^{45,306} Peripheral blood lymphocytes actually decrease in the first 2 to 3 days of an RV cold, and migration of lymphocytes into the nasal secretions increases at this time.^{45,192} Specific humoral antibody usually is not present in the serum or nasopharynx this early in the illness, a finding suggesting that these *in situ* nasopharyngeal lymphocytes, through cell-mediated immunity, play an important role in controlling RV proliferation. RV infection of primary epithelial cells cultured *in vitro* leads to increased expression of the T-cell attractant molecule CXCL10; and activated T cells cocultured with the epithelial cells produce IFN- γ and tumor necrosis factor (TNF) and activate the nitric oxide pathway, which can help inhibit viral replication.¹⁷² Hsia and colleagues¹⁵⁶ examined the ability of peripheral blood lymphocytes to liberate various cytokines (IL-2 and IFN- γ) and participate in other cellular immune processes (cytotoxicity and antigen-stimulated blastogenesis) during the early days of RV colds in experimentally infected human volunteers. These investigators found that all these cell-mediated immunity activities during infection were increased significantly when compared with preinfection levels. Of special interest, the cellular ability to liberate higher levels of IL-2 correlated inversely and significantly ($P < .02$) with virus shedding and nasal mucus production. Cross-reactive T-cell epitopes are shared by RVs, and T cells isolated from peripheral blood and from tonsillar tissue proliferate and secrete a variety of cytokines (IFN- γ , IL-2, IL-4, IL-5, IL-13) after exposure to RV antigens.^{113,140,273,305} Thus activation of T cells may contribute not only to virus clearance but also to airway inflammation.¹¹³

Interference Among Rhinoviruses

Interference in infection with heterotypic RV serotypes, which lasts between 5 and 16 weeks, has been reported in human volunteers.⁹⁷ Complete resistance to infection was observed after inoculation with as much as 2000 TCID₅₀ of RV-16 (administered by nasopharyngeal spray) in a subject with an unsuspected “wild” RV (not typed) infection present at the time of inoculation.¹⁹⁰ However, epidemiologic studies in a nursery school population,²⁸ a military population,²⁵⁴ and a family population²¹⁴ showed sequential heterotypic RV infections occurring frequently, sometimes at intervals as short as 2 days. In the family population, one subject was infected by three different RVs within a 30-day period. The factor or factors responsible for the interference observed in the experimental human infection model have not been identified. Simultaneous infection with an RV and other respiratory viruses, including influenza A and B viruses, coronaviruses, parainfluenza type 1 virus, respiratory syncytial virus (RSV), adenoviruses, various enteroviruses, or other RV serotypes, also has been commonly reported, particularly in children.^{90,104,202} However, coinfection with some other respiratory viruses (e.g., RSV) is less frequent than expected using molecular diagnostic assays, suggesting that these viruses may specifically suppress coinfection with each other.^{175,202}

Influence of a Cold Environment on the Course of Infection

Exposure to cold temperatures has been thought either to initiate or to exacerbate respiratory tract infections. In fact, chilling animals was shown to increase the severity and frequency of viral infection.²⁹⁹ However, investigation of the effects of chilling on humans infected with “common cold viruses” and with RV-15 did not demonstrate significant effects.⁸⁵ In the RV-15 experiments, the conditions were realistic. The subjects (men) were cooled sufficiently in air to cause shivering for approximately an hour or were immersed in water long enough to cause a decline in rectal temperature.

Effect of Age and Sex

A much higher prevalence of RV infection is found in infants and young children than in older persons. In Seattle,¹⁰³ the RV infection rate in children from birth to 5 years of age was nearly twice that of older children and adults (0.77 vs. 0.41 infections per person per year, respectively); in Tecumseh,²²⁰ the isolation rate in the 1- to 4-year-old group was far higher than that in any other age bracket. The high attack

FIG. 167.5 Number of respiratory viruses identified using polymerase chain reaction from 318 respiratory tract illnesses in children attending a group child care center. HRV, Human rhinovirus; Ad, adenovirus; CoV, coronavirus; PIV, parainfluenza virus types 1 to 4; RSV, respiratory syncytial virus; HMPV, human metapneumovirus; Flu, influenza A and B. (Modified from Fairchok MP, Martin ET, Chambers S, et al. Epidemiology of viral respiratory tract infections in a prospective cohort of infants and toddlers attending daycare. *J Clin Virol.* 2010;49:16-20.)

rates in these young children were not unexpected because fewer than 10% of them would have been expected to have antibody to any of the 56 RV types,¹²⁸ and children ordinarily are subjected continuously to the family-like environment so conducive to transmission of RVs. Even higher prevalence rates among young children have been observed when molecular methods have been used for diagnosis; 34% of samples from children younger than 5 years were RV positive compared with 6% of samples from adults in a 1-year surveillance study of families in Utah.³⁹ In especially crowded populations, attack rates may be high. In an Alaskan Native village, 70% of 395 children were infected during a spring outbreak of RV-16 infection.³¹²

The frequency of infection with RV generally declines throughout life. In a prospective study of children attending group child care where PCR methods were used to analyze samples collected weekly in symptomatic children, RVs were the most common respiratory virus identified (Fig. 167.5), and the incidence/child-year of RV infection was 1.3 per year for children enrolled in group child care at birth to 12 months of age versus 0.8 for children older than 12 to 24 months.⁹⁵ Beginning at the age of school attendance, the number of RV infections declines gradually from one to two per year to 0.25 per year in the age group older than 60 years.^{128,222} Results from most laboratories have found that persons 20 to 30 years of age account for an exception to the general decline in incidence with age^{103,148,219,222}; RV infections, as well as infections with other respiratory pathogens, increase during this period of life. Because the increase is especially marked in mothers,^{103,148} it probably is the result of the transfer of respiratory illness in small children to parents.

In Tecumseh, the number of respiratory illnesses per year was consistently higher for female patients than for male patients (3 to >60 years of age).²²² If one assumed that RVs account for a similar proportion of disease in each gender, this finding would indicate that girls and women generally have more RV infections. As noted earlier, women with young children clearly seem to have more RV infections than do others in their age group. In Seattle,¹⁰³ mothers had 1.5 times more RV infections than fathers did, and in Charlottesville, women of childbearing age had approximately 1.2 times more RV illness than male study subjects did.¹²⁸

The number of moderate to severe RV illnesses was higher in boys than girls during the first 3 years of life in a longitudinal birth cohort study examining factors associated with developing wheezing illness.²⁹⁴ However, the number of RV-associated wheezing illnesses was similar between the two sexes.

Effect of Psychosocial Factors

Numerous psychosocial factors have been shown to influence susceptibility to RV infection, primarily in the experimental human infection model.

Increased psychological stress, as measured by numerous stress indices, and poorer sleep efficiency and sleep duration were associated with an increased susceptibility to infection and an increased likelihood of developing illness.^{56,58,60,242} In contrast, having a more diverse societal network (increased number of social ties) and having a positive emotional style (i.e., sense of well-being, vigor, and calmness) were associated with resistance to infection and illness.^{57,88} Antibody-negative (serum antibody levels <1:2) subjects were equally susceptible to infection regardless of the degree of stress or number of social ties, although these factors did influence the likelihood of clinical illness.^{57,58} Increased stress in working adults also was associated with an increased risk for having a natural common cold.²⁷⁸ Increased life stress also has been associated with glucocorticoid receptor resistance and an increased likelihood of illness following experimental RV challenge; the greater glucocorticoid receptor resistance also was associated with the production of higher levels of proinflammatory cytokines among RV-infected persons.⁵⁹

CLINICAL MANIFESTATIONS

RV infections in any age group usually cause only mild upper respiratory tract illness or common colds. Investigators estimate that RVs cause 30% to 50% of common colds, at least in adults.¹⁹⁵ A variety of respiratory symptoms and signs can be present, and the relative frequency of such symptoms varies between children and adults (Table 167.2). The development of serious illness is also possible: RV-associated, radiograph-positive, atypical pneumonia has been described in military trainees¹¹¹ and in immunocompromised adults^{119,158,166}; graft dysfunction has occurred in lung transplant recipients¹⁷⁴; and exacerbation of underlying lung disease has been seen in adults with asthma and chronic obstructive pulmonary disease.^{20,264} Severe respiratory disease, pneumonia, and death also have occurred in outbreaks of RV infection in geriatric patients residing in nursing homes.^{152,194}

Children, particularly the very young, are subject to serious, sometimes fatal RV-caused illnesses. These include bronchiolitis and pneumonia. Viremia has been noted to occur in children with RV infection and

respiratory disease.^{94,313} Deaths of infants with rhinoviremia has also been observed, including one that occurred during a cold, and six “cot” deaths that were diagnosed as bronchiolitis/pneumonia and from which RVs were isolated.^{253,296} At least in theory, generalized illness after viremia seems possible with RV infections; the RVs are a division of the larger picornavirus group, which contains many viruses capable of generalized and fatal infection and whose genomes have considerable homology with the RVs (see [Structure of the Virion](#), earlier). RVs have also been isolated from patients with a variety of other respiratory clinical illnesses, including pharyngitis, epiglottitis, and laryngotracheobronchitis (croup) (Table 167.3). However, detection of RV may also occur in persons who are totally asymptomatic; up to 25% of infections detected by PCR assay in otherwise healthy children and adults are asymptomatic or subclinical,^{159,268} and asymptomatic shedding for up to 3 months has been documented in immunocompromised hematopoietic stem cell transplant recipients.²¹⁰

Rhinovirus Infections in Hospitalized Children

Many investigators have identified RV infections in children hospitalized with severe respiratory disease, and these studies continue to illustrate the high number of hospitalizations associated with RV in children overall. In 1971 in Bristol, England, before the widespread use of molecular diagnostic tools, 377 infants hospitalized for respiratory disease yielded 199 (53%) viral diagnoses.¹⁶⁵ RSV was the predominant virus, but RVs were second most common at 12% (23 patients). RV illnesses were comparable in severity to those caused by RSV.

At St. Anna Children's Hospital in Vienna, Kellner and colleagues¹⁷⁸ compared the clinical features of RV and RSV infection in 519 children aged 10 days to 3 years (median age, 6.6 months) from 1984 to 1986. Viral pathogens were detected in 227 (44%) of the children; and of these, 119 (23%) were RSV and 60 (12%) were RV. The physical findings (Table 167.4) and the clinical diagnosis (see Table 167.3) of the children with RV or RSV infection were the same, except RV infections were

RV, Rhinovirus; RSV, respiratory syncytial virus.

Modified from Kellner G, Popow-Kraupp T, Kundi M, et al. Clinical manifestations of respiratory tract infections due to respiratory syncytial virus and rhinoviruses in hospitalized children. *Acta Paediatr Scand*. 1989;78:390-394.

more likely than were RSV infections to be associated with upper respiratory tract infection.

Glezen and colleagues¹²¹ performed a prospective study to evaluate the occurrence of respiratory virus infection in subjects with respiratory or cardiac disorders in Houston, Texas, between 1991 and 1995. RV infections were identified by culture in 51 subjects from a total of 1198 evaluated illnesses; six were associated with a second respiratory virus infection.⁹³ In children younger than 5 years of age, exacerbation of asthma, bronchiolitis, and suspected sepsis were the most common clinical findings, whereas nearly all older children and young adults had an exacerbation of asthma. In older adults, a complication of an underlying disease (asthma, chronic obstructive lung disease, congestive heart failure) or pneumonia was diagnosed. In this prospective study, RV infections were an important cause of lower respiratory tract illness in all age groups.⁹³ When molecular methods were subsequently used to identify viral respiratory tract infections from specimens collected during this study, RVs were present in almost 25% of analyzed samples and in approximately half of children younger than 1 year of age.²¹

Studies of RV in hospitalized children with respiratory disease using molecular diagnostic techniques around the world document high rates of RV. In a large multicenter US study of children younger than 5 years, RV was detected in 17.4% of 1947 children hospitalized with acute respiratory illnesses compared with 12.5% of controls.¹⁵⁹ RV A viruses were significantly more common in hospitalized children 24 months and older compared with controls (8.1% vs. 2.2%), and RV C infection was significantly more frequent in hospitalized children 6 months and older (8.2% vs. 3.9%). RV B infection was uncommon in both groups (<1% each). RV has also been commonly detected at high rates in diverse geographic settings. Detection of RV was similar in hospitalized South African children infected or not infected with HIV with pneumonia (45.6%) or bronchiolitis (52%).⁹ RV was detected in 44% of Alaska Native children hospitalized in Alaska compared with 16% of healthy controls.²⁶⁸

Bronchiolitis is one of the more common reasons for young children to be hospitalized with respiratory illness. RVs have been identified in several studies as the second most common virus infection identified in association with bronchiolitis after RSV.^{42,167,199,200} In some studies, the bronchiolitis associated with RV infection was less severe than that caused by RSV,^{199,200,203,274} whereas in others the severity was similar.⁴² In a large multicenter study reported by Mansbach and colleagues,¹⁹⁹

children younger than 2 years and coinfecting with RSV and RV had significantly longer lengths of stay after adjustment for clinical and demographic parameters, whereas RV coinfections with other respiratory viruses were not associated with prolonged lengths of stay. Decreased severity of illness in hospitalized children who are coinfecting with both RV and RSV or human metapneumovirus has also been documented.^{33,203}

The contribution of RV to community-based illness has become both more sensitive and more practical with the advent of multiplex PCR. A prospective weekly sampling in 26 families with young children demonstrated that RV was the most common virus detected in any age group and represented 34% of the viral detection by week in children younger than 4 years.³⁹ Similarly, the burden of RV in children seeking care in a pediatric emergency department has been documented to be the most frequent respiratory virus detected in children younger than 3 years seeking acute care, with 59% of 425 children having lower respiratory tract disease, 52% requiring hospitalization, and 22% hospitalized for 3 or more days.⁵⁵ In this study, coinfection increased the risk for lower respiratory tract infection (odds ratio, 1.83; 95% confidence interval, 1.01–3.32).

Several studies have examined the prevalence of RV infection in pediatric patients presenting or hospitalized with community-acquired pneumonia. Juven and colleagues¹⁷³ found RV infection in 25% of 254 children hospitalized with community-acquired pneumonia; a concomitant bacterial copathogen was identified in half of the patients. Tsolia and associates²⁸² reported RV infection in 45% of 75 school-aged children hospitalized with community-acquired pneumonia, with a copathogen found in 58% of the RV-infected patients. García-García and colleagues¹⁰⁹ detected RV infection in approximately 20% of children hospitalized with pneumonia; RV was the most common viral pathogen identified in children older than 18 months of age and the sole virus identified in 55% of the RV-infected patients. Self and colleagues²⁶⁵ performed a case-control study in Salt Lake City, Utah, and Nashville, Tennessee, to evaluate the importance of RV detection in pediatric patients with community-acquired pneumonia; RV infection was identified in 17% of controls compared with 22% of patients with community-acquired pneumonia, and its presence was not significantly associated with pneumonia. These indicate the need to account for background circulation of respiratory viruses among symptom-free subjects investigating the causes of pneumonia.

In summary, there is substantial evidence that RVs can cause serious lower respiratory tract illness, especially in young children. In some populations, RVs may be second to RSV in frequency and be associated with comparably severe signs and symptoms. However, the prevalence of asymptomatic virus shedding and the frequent identification of another viral respiratory tract infection make it difficult to determine the clinical significance of RV infection in the individual patient.

Asthma

RV infection is a risk factor both for the development of asthma and for exacerbations of wheezing in children with asthma. Having either an RSV or an RV infection that results in a wheezing illness during the first year of life is an independent risk factor for wheezing later in childhood.^{183,186,191} Children who have a RV-associated wheezing illness in the first 3 years of life are more likely to be diagnosed with asthma at 6 years of age than are those who have an RSV-associated illness.¹⁶² Sensitization to aeroallergens (atopy) in the first year of life also is an independent risk factor for the subsequent development of asthma, particularly after RV infection and precedes RV-induced wheezing.^{160-162,186} Genetic factors also influence susceptibility to RV-induced wheezing.⁴¹

Viral respiratory tract infection is a common precipitant of wheezing in children with asthma.³⁷ RVs are the most frequent respiratory virus identified in children with acute wheezing exacerbation of asthma; however, not all RV infections in an asthmatic child will result in wheezing. Two investigative groups serotyped the RVs isolated from children with wheezy illness and found no types to be particularly “asthmagenic”; and a total of 30 different serotypes were associated with asthma exacerbations.^{176,211-213} It is not clear whether RV strain differences are important factors in precipitating asthma attacks, although one small study found an increased risk for exacerbation with minor group RV A strains.⁷⁰ Strain differences in the level of cytokine and chemokine induction following infection of bronchial epithelial cells has also been reported.³⁰¹

The mechanism of bronchospasm in virus-infected patients is an area of great research interest. RVs replicate in the lower respiratory tract.^{114,230} RV infection induces the production of numerous proinflammatory cytokines in both the upper and lower airways, and an increased number of inflammatory cells has been demonstrated in the lower respiratory tract in association with RV infection.^{99,107,112} The presence of activated cytotoxic T cells in the lower airways has been suggested to contribute to asthma-associated mortality.²²⁶ Host factors also play a role, in that innate immune responses to RV are impaired. For example, bronchial epithelial cells from asthmatic individuals produce less IFN- β and have less apoptosis and greater viral replication after infection with RV than do cells from nonasthmatic subjects or in those with well-controlled asthma.^{277,302} The timing of interferon expression during the course of RV infection may also be important.²⁶³ Aeroallergen-sensitized asthmatic children have higher expression of the high-affinity IgE receptor Fc ϵ RI than nonallergic, nonasthmatic children, and this was associated with a decreased production of IFN- α and IFN- γ 1 by plasma-derived dendritic cells after RV stimulation.⁹¹ IFN production was further decreased after cross-linking of the Fc ϵ RI receptor. Animal models also suggest the possibility that reflex neurogenic pathways may be activated in association with viral respiratory tract infection and may lead to bronchoconstriction. The pathogenesis of respiratory virus-induced bronchospasm is an area of active research, with the hope that preventive or therapeutic intervention strategies can be developed.

Otitis Media

Although acute otitis media is chiefly a bacterial disease, with approximately two-thirds of middle ear fluid specimens yielding *Streptococcus pneumoniae*, *Haemophilus influenzae*, or both, and *Moraxella catarrhalis* and other bacteria playing lesser roles, otitic involvement often is preceded or accompanied by a putative viral upper respiratory tract illness.^{12,14,181,260,251} Most bacterial pathogens found in middle ear fluid are colonizers of the nasopharynx, and bacterial infection of the middle ear is considered to be a direct extension from that area.¹⁸¹ A history of a preceding viral upper respiratory tract illness is common, and clear and comprehensive evidence of viral extension from the nasopharynx

to the middle ear has been established. Many different respiratory viruses have been identified in middle ear effusions from children with otitis media, and RVs are one of the most commonly identified when molecular methods of detection are used. Pitkaranta and colleagues²³⁹ identified respiratory viruses from the middle ear effusions in 30% of 100 children who had otitis media with effusion. RVs constituted approximately two-thirds of the respiratory viruses identified. Bacterial pathogens were identified in 35% of the samples, and both bacteria and viruses were found in 11%. A criterion for selection was the absence of an upper respiratory tract illness within the preceding week; thus whether the presence of RV RNA represented evidence of ongoing or past infection is unclear. Blomqvist and colleagues²⁹ found RV RNA in middle ear effusions from 41% of children with otitis media in the first 2 years of life, and Chantzi and colleagues⁴⁹ found a similar prevalence of RV RNA in otitis media effusions.

The presence of both bacterial and viral pathogens in middle ear fluid does not, in general, interfere with the effectiveness of antibacterial therapy, although in those specific patients whose acute otitis media is refractory to treatment it may.¹⁵ When measured against a comparison group of 66 “normal” acute otitis media cases (controls), 22 patients with refractory cases harbored significantly more viral pathogens than did controls (68% vs. 41%, respectively; $P < .05$). In addition, when only the middle ear fluid of these groups was examined for the presence of viruses, 32% of patients with refractory cases had virus versus 15% of controls. RVs were the dominant viruses in both groups. Bacterial pathogens were grown from the middle ear fluid of four of the 22 in the poor-responder group, and all harbored concomitant respiratory viruses, two of which were RVs; only one of the four bacteria was resistant to the antibacterial agent used in therapy. These investigators also examined patients in the 66-patient control group whose illnesses were refractory to treatment and found significantly more viruses ($P < .05$) in the middle ear fluid of this group than in those with a good response to therapy. These authors concluded that the presence of viruses in the middle ear fluid of children with acute otitis media can delay response to antibacterial therapy.

Chonmaitree and associates⁵³ in Galveston, Texas, also investigated the role of viruses in middle ear fluid as agents that may interfere with antibacterial therapy. In their initial report, viruses were cultured from the middle ear fluid of 11 of 58 children (19%); RSV and RV were the most frequent viruses isolated, at 3 each. Of the patients in whom therapy failed, significantly more ($P < .05$) harbored viruses as well, and of those whose bacteria were susceptible to the treatment antibiotic, significantly more had combined viral-bacterial infections. In two subsequent reports by these authors, the highest rate of poor bacteriologic outcome occurred when RV was isolated from middle ear fluid. Seven of nine instances of RV infection resulted in bacteriologic treatment failure.²⁷⁶ Subsequent studies using molecular techniques by Chonmaitree and colleagues⁵² found that acute otitis media does not occur after asymptomatic RV infection and that RV viral load in respiratory specimens is not a risk factor for the development of acute otitis media.

These studies suggest that viruses, including RVs, play a role in acute otitis media, especially in prolonging the response to antimicrobial treatment. McBride and associates²⁰⁴ at the University of Pittsburgh and the University of Virginia used RV-infected human volunteers and found that the eustachian tube became occluded in 50% of the volunteers and that abnormal middle ear pressure was present for as long as 10 days. These studies were extended by Buchman and colleagues,³⁵ who inoculated 60 volunteers with RV-39. Middle ear pressures of less than -100 mm H $_2$ O were noted in 22 subjects (37%). In two of the three subjects who had pressures less than -100 mm H $_2$ O, upper respiratory tract illness with middle ear effusion developed. In this study, the otologic manifestations of experimental RV infection were extended to include otitis media.

Arora and colleagues¹³ examined the role of viruses in 61 children (mean age, 3.2 years) with subacute or chronic asymptomatic otitis media with effusion. Five RVs and one adenovirus were found in the middle ear fluid. In addition, bacterial pathogens were isolated from the patient with adenovirus infection and from two of the patients with RV infection. None of these patients with otitis media and effusion were ill with an upper respiratory tract infection at the time the specimen

was obtained, and the effusion had endured 30 to 60 days before myringotomy was performed.

Sinusitis

RVs can cause a clinical syndrome of rhinosinusitis similar to that caused by bacterial infection. Gwaltney and colleagues¹³² performed computed tomography of the sinuses on adults with acute common colds of less than 4 days' duration in which RV infection was documented by culture in 27%. Radiographic abnormalities included mucosal thickening and air-fluid levels. Associated clinical signs and symptoms resolved without antibiotic therapy, a finding suggesting that the radiographic signs were caused by an acute viral infection. Few attempts have been made to recover viruses directly from the sinuses. Two reports from Virginia noted that 140 aspirates obtained by direct puncture of the maxillary sinuses yielded 86 positive specimens, and seven of 12 viruses were RVs.^{133,134} Pitkaranta and associates^{238,240} used real-time PCR analysis and in situ hybridization to identify RVs in 50% of adults with acute community-acquired sinusitis. A prospective, longitudinal pediatric study of acute bacterial sinusitis and viral respiratory infections in children younger than 3 years demonstrated that viruses were detected in 63% of children during the initial upper respiratory infection visit, and RV detection was positively correlated with the risk for acute sinusitis ($P = .01$).²⁰¹ Because the signs and symptoms of viral rhinosinusitis and bacterial sinusitis can be difficult to distinguish, the American Academy of Pediatrics developed clinical practice guidelines for the diagnosis and treatment of bacterial sinusitis, and these were updated in 2012 by the Infectious Diseases Society of America.^{4,54}

Immunocompromised Patients

RV is the most common respiratory virus detected in immunocompromised patients. A cumulative 100-day incidence of 22.3% and 1-year incidence of 31% have been reported in hematopoietic stem cell transplant recipients in a prospective study conducted in Seattle.²¹⁰ Infections occurred year-round, and prolonged virus shedding for more than 12 weeks was noted. Clinical manifestations can range from mild upper respiratory tract symptoms to fatal pneumonia.^{119,126,210} Fever, cough, sputum production, and dyspnea are the most common symptoms in hematopoietic stem cell transplant recipients with RV detected in the lower respiratory tract.¹⁶⁶

When RV is identified as the sole pathogen in a transplant recipient with lower respiratory tract infection, it can cause severe pneumonia with a clinical picture similar to that of influenza virus-associated pneumonia.⁵¹ A mortality rate of more than 40% was documented in a study of 87 patients with laboratory-proven RV detected in bronchoalveolar lavage fluid with symptomatic lower respiratory tract disease; risk factors for poor outcome included oxygen use at RV diagnosis (hazard ratio [HR] 2.6; $P = .04$), steroid use more than 1 mg/kg before diagnosis (HR, 5.5; $P = .002$), and bone marrow as a stem cell source (HR, 2.3; $P = .05$).²⁶⁶ Many immunocompromised patients with fatal infections have been coinfecting with other pathogens, making it difficult to determine the relative contribution of RV infection to the outcome.^{119,158} Overall, higher viral loads in clinical samples correlated with more symptomatic and more severe disease.^{118,210}

DIAGNOSIS OF INFECTION

RV infections cannot be diagnosed solely on the basis of clinical grounds because they cause such a wide spectrum of respiratory illness, particularly in infants, children, and immunocompromised hosts. However, because of the characteristic spring-summer-fall seasonal pattern of the RVs, tentatively assigning an RV origin in patients with mild to moderate respiratory illness during these months is reasonable.

Classical methods for diagnosis of RV have been based on culture, but culture of RV can be difficult. These viruses propagate unpredictably, even in relatively sensitive diploid cell cultures such as WI-38 and FT cells or in Ohio strain HeLa cells, and organ cultures or cultures of differentiated airway epithelial cells at an air-liquid interface are needed to propagate RV C strains in vitro.^{19,32,66} Isolation of RV from children can also be hampered by the common practice of relying on a throat swab, which may contain only one tissue culture infectious

TABLE 167.5 Quantity of Virus Found in 87 Throat Swabs From Children Aged 3 to 11 Years: Madison, Wisconsin, 1971–72^a

virus particle or less (Table 167.5). Hendley and colleagues¹⁴⁸ found nasal specimens to be superior for RV diagnosis, with nasal aspirates successfully used worldwide.^{155,177,208} If freezing is necessary and dry ice is used, great care must be taken to avoid contamination of the specimen with sublimed carbon dioxide because the resultant carbonic acid rapidly kills the virus. Cell cultures should be incubated and slowly rolled at 33°C. Evidence of viral growth usually is seen between 2 days and 2 weeks.

The availability of rapid, sensitive multiplex PCR assays in diagnostic laboratories has revolutionized the diagnosis of RV in the hospital and clinic. Because RVs have many nucleotide sequences in common among the RNA genomes of the various serotypes, especially in the noncoding region at the 5' end, reverse transcriptase (RT)-PCR assays have been designed and widely used for the detection of RVs, often in panels with other respiratory viruses.^{22,237} Some assays do not distinguish RVs from enteroviruses, whereas others are RV specific.^{21,227} The superiority of RT-PCR techniques compared with cell culture methods first became evident in a clinical study of children with acute respiratory illnesses. Johnston and colleagues¹⁷¹ detected RV by PCR in 146 of 292 samples (50%) that yielded RV in only 47 (16%) by standard culture. Many subsequent studies confirmed the superiority of RT-PCR assays over culture methods for the detection of RVs.^{18,20,157} The increased sensitivity of molecular assays can make interpretation of a positive result problematic because many asymptomatic infections are identified. Viral quantitation may have a role in identifying clinically significant RV infections.^{55,118}

PREVENTION AND TREATMENT

Prevention and treatment are addressed thoroughly in Chapter 7 and elsewhere, and only measures specific to the RVs are added here. Although some protection after the use of inactivated vaccines has been demonstrated,^{84,234} the existence of more than 100 serotypes limits the prospect of vaccine development. However, based on the observation that cross-reacting neutralizing epitopes have been identified among the RVs, developing a vaccine that targets these epitopes may be possible.^{92,120}

The most effective RV cold-preventive agent described to date that has been demonstrated to be effective for natural RV colds is IFN-α, a protein produced as part of the host's natural antiviral defense and now produced for experimentation by genetic recombinant methods.⁸⁷ Investigators administered this agent by nasal spray to other family members after symptoms appeared in the index case; 80% of the secondary RV colds were prevented. However, IFN given in this fashion does not seem to be effective against other respiratory viruses. For example, in a follow-up study in Seattle, IFN-α did not reduce the incidence of colds when administered in a protocol identical to that used in the previous family studies, chiefly because RV infections were not the majority of agents causing colds.^{81,87,106} RVs often have a decided seasonality, so rapid diagnosis of the index case by PCR analysis might be helpful to determine when IFN-α could be used effectively to stop intrafamily spread. The disadvantage of IFN prophylaxis is that prolonged intranasal administration (>7 days) or repeated treatment produces an inflammatory response consisting of nasal stuffiness, ulceration, and blood-tinged discharge.²⁶¹

Numerous antiviral agents with in vitro activity against RVs have been developed. The earlier section in this chapter on structure of the

virion describes the development of some of these agents, which was made possible by taking advantage of current detailed knowledge of RV structure and specific cell receptors. Several of these preparations, including capsid-binding agents, soluble receptor (soluble ICAM-1), and antibody to the receptor (ICAM-1), have been tested in clinical trials, but development of most of these agents has not been pursued for a variety of reasons,^{23,289} as reviewed by Arruda and Hayden.¹⁷ Another capsid-binding agent, pleconaril, has in vitro antiviral activity against many enteroviruses and RVs, and phase III clinical trials on naturally acquired colds demonstrated some reduction in the severity and duration of several respiratory symptoms.¹⁴² However, pleconaril induces the CYP3A4 enzyme that can lead to menstrual irregularities in women taking oral contraceptives.⁹⁸ This concern, along with the drug's modest efficacy, prevented pleconaril from being approved by the US Food and Drug Administration. Vapendavir is another capsid-binding agent in clinical trial; a phase 2 clinical trial in asthmatic adults demonstrated more rapid improvement in upper respiratory symptoms, better respiratory function, and decreased virus shedding compared with placebo.¹⁴¹ However, early results of the SPIRITUS clinical trial conducted in adults with asthma did not demonstrate significant clinical improvement in asthma control compared with placebo based on questionnaire completion at study day 14. Whether to conduct further clinical studies of this agent is under consideration by its developer.

Rupintrivir, another class of antiviral drug for RVs, is a potent, irreversible inhibitor of viral 3C protease and has been administered as an intranasal drug; however, it had only moderate antiviral and clinical efficacy in a phase II clinical trial, and further development has been halted.¹⁴³

Colds usually are treated symptomatically with mild nonsteroidal antiinflammatory drugs, sympathomimetics (e.g., phenylpropanolamine), and antihistamines; these agents are discussed in Chapter 7.²⁷¹ Anticholinergic agents (e.g., topical ipratropium bromide) and first-generation antihistamines reduce severity of rhinorrhea, whereas second-generation ("nonsedating") antihistamines have no effect. The efficacy of the first-generation antihistamines may result from the ability of these agents to block muscarinic as well as histaminic receptors and to cross the blood-brain barrier.²²³ Sympathomimetics decrease nasal obstruction, although topical administration may lead to rebound nasal obstruction. Nonsteroidal antiinflammatory agents decrease the severity of some of the systemic symptoms associated with colds (e.g., malaise, headache).²⁸⁴ A combination of antiviral and antimeediator preparations may provide effective therapy. Various other treatments, including vitamin C,^{48,146} *Echinacea*,^{207,285} intranasal humidified air,^{101,291} and zinc lozenges,^{163,198,241} have been evaluated, and some studies have reported a clinical benefit, although other studies have failed to confirm such findings.²⁸⁴ Almost all clinical evaluations of symptomatic and alternative therapies have been performed in adults; very few data exist on the utility of such therapy in children.^{198,270} In 2007, the US Food and Drug Administration released a warning against using over-the-counter therapies including antihistamines, decongestants, and antitussives for the treatment of the common cold in children younger than 2 years because of potentially dangerous side effects linked to several deaths, in the absence of data demonstrating benefit in this age group.¹⁰⁰

The use of oral or inhaled corticosteroids appears to enhance the shedding of viable virus.^{125,248} One potential consequence of corticosteroid use, seen in a study of pediatric patients with a common cold syndrome, is a significant increase in the risk for developing acute otitis media in RV-infected subjects.²⁵⁹ However, hospitalized children with a first episode of wheezing associated with RV infection were less likely to have recurrent wheezing over the following year if treated with prednisolone, and corticosteroid therapy can decrease the duration of symptoms associated with acute asthma exacerbations.^{168,189} Available evidence indicates that corticosteroids do not have a role in the treatment of uncomplicated RV infections. Similarly, no role exists for the use of antibiotic therapy in uncomplicated RV infection.

Hepatitis A Virus

Yen H. Pham • Daniel H. Leung

HISTORY

Hepatitis A has been recognized as a clinical entity for centuries, notably as large epidemics of jaundice among military camps in both ancient and modern times. During the past several decades, epidemiologic and clinical studies have defined the infectious nature of the disease, leading to the differentiation of “infectious hepatitis,” now known as hepatitis A.²⁰⁶ In the 1970s, isolation of hepatitis A virus (HAV) and identification by immune electron microscopy among stool samples of patients with HAV¹³³ led to understanding of the fecal-oral route of transmission, the clinical course of infection, and the efficacy of immunoglobulin in preventing disease.^{206,207,423} This hastened the development of serologic tests that differentiate acute and resolved infections, definitions of pathogenic events during infection, and further epidemiologic study of HAV infection. Following propagation of HAV in cell culture,^{88,304,404,406} the evolution and licensure of highly effective vaccines have dramatically changed the landscape of HAV infection, though certainly not eradicated it.^{61,264,408}

PROPERTIES

Classification

HAV is a 27-nm, nonenveloped, positive-sense RNA virus belonging to the family Picornaviridae. Although HAV initially was classified in the genus *Enterovirus*, nucleotide analysis indicates that HAV is distinct from all other picornaviruses.^{222,225,395,416} In contrast to other enteroviruses, HAV has essentially no nucleotide or amino acid homology, does not have an intestinal replication phase, replicates slowly in cell culture, rarely produces a cytopathic effect, and is relatively resistant to inactivation by heating.⁸⁷ For these reasons, HAV has been reclassified in a separate genus designated *Hepatovirus*.^{257,416}

Genomic Organization and Genetic Variation

Hepatitis A is composed of an icosahedral capsid that contains a positive-sense, single-stranded RNA genome of approximately 7.5 kb in length with a single open reading frame flanked by 5′ and 3′ untranslated regions (UTR). The 5′ UTR is the most conserved region of the genome and contains an internal ribosome entry site. The open reading frame encodes a polyprotein organized into three functional regions: P1, P2, and P3. P1 is secondarily cleaved into four capsid proteins, VP1 to VP4, whereas P2 and P3 proteins encode nonstructural proteins associated with replication.^{222,225,363,405,406,416}

HAV exists as a single serotype. The neutralization site appears to be conformational and derived from epitopes located on VP1 and VP3, as identified by neutralizing monoclonal antibodies.^{268,299} A high degree of nucleotide conservation exists among geographically diverse human HAV isolates. However, enough genetic diversity exists to define several HAV genotypes and subgenotypes. The entire nucleic acid sequences of several HAV strains have been determined by molecular cloning, and a large number of HAV isolates have been characterized by sequencing of short genome segments.²⁷⁰

The genomic regions most commonly used to define HAV genotypes include (1) the C terminus of the VP3 region, (2) the N terminus of the VP1 region, (3) the junction of the VP1 and P2A regions, and (4) the VP1-P2B regions and the entire VP1 region (Fig. 168.1).^{81,270}

Six genotypes (I to VI) are now defined based on analysis of the 900 nucleotides of the complete VP1 protein. Only genotypes I, II, and III, divided into subtypes A and B, infect humans. The other three (IV, V, and VI) appear to be restricted in their primary replication to Old World monkeys.^{269,376}

The worldwide geographic distribution of HAV serotypes has been well described.^{81,270,315} Genotype I is the most prevalent worldwide, particularly genotype IA, which dominates in North, Central, and South

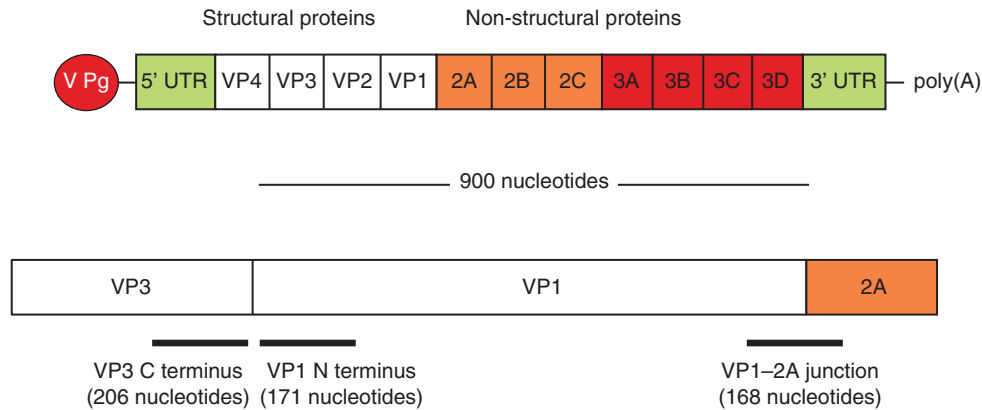

Fig. 168.1 Genomic organization of hepatitis A virus.

America; China; Japan; Thailand; and Europe.^{48,177,184,315} Subgenotype IB is reported mainly from the Mediterranean region and South Africa and is the most prevalent in Turkey.²⁷⁸ Subgenotype IIIA is the most prevalent in India, Nepal, and Korea.^{170,348,421} In low-endemicity areas, such as the United States and Western Europe, subgenotype IA dominates, although all genotypes have been reported.^{82,270} Of note, subgenotypes IIA, IIB, and IIIB rarely have been reported.¹⁰²

The analysis of the other genomic regions (i.e., the N terminus of the VP1, VP1-2B regions, the entire VP, and the C terminus of VP3) allows better strain discrimination. Growing sequence databases allow for the identification of the geographic origin of a given subgenotype. This genetic variation has proved useful in identifying clusters and linking apparently sporadic cases.^{10,101,167,172,267,313}

Genotype does not appear to influence the clinical presentation or outcome of infection,^{2,144,170} although outbreaks in Korea suggest that genotypes might account for differences in disease severity. Report of a national hepatitis A outbreak in Korea from 2006 to 2008 indicated that genotype IIIA infection demonstrated significantly higher transaminase levels, prothrombin time, and leukocyte count, with more severe symptoms including fever and dark urine on admission compared to genotype IA infection.⁴²¹ Similarly, another Korean study found genotype IIIA to be associated with higher alanine transaminase (ALT) levels and longer hospitalization among adolescents and young adults in a multivariate logistic regression model.⁴¹⁹

Virulence

HAV is known to produce disease in humans and nonhuman primates. HAV replicates more slowly in cell culture than other picornaviruses, and wild-type viruses may require many weeks of adaptation or serial passages before infectious foci or HAV antigen is detected.^{33,219,222,284,342} With increasing passage in cell culture, the virus adapts to growth in vitro with more rapid production of viral antigen and increasing virus titers. HAV produces a high ratio of defective to complete (infectious) virus both in cell culture and during infection.^{43,416} Cell culture adaptation is associated with mutations in nonstructural proteins and the 5' nontranslated region.^{121,123} Mutations in the VP1/2A and 2C genes are associated with loss of virulence, but virulence can be restored if genes from the wild-type virus are reintroduced.¹²² Cell culture-adapted HAV rarely produces a cytopathic effect, although cytopathic strains have been isolated and serve as a useful model for laboratory studies.^{88,272}

The HAV virion appears to be extremely stable, although the molecular determinants of this characteristic are not known. HAV is stable in the environment, with only a 100-fold decline in infectivity when it is stored for longer than 4 weeks at room temperature.^{87,246,247,294} The virus retains infectivity even when treated with nonionic detergents, organic solvents, and low pH at 38°C (100.4°F) for 90 minutes.^{87,256} HAV is more resistant than poliovirus to heat in that it is inactivated

Transmission of Hepatitis A

FIG. 168.2 Transmission of hepatitis A.

only partially at 60°C (140°F) for 1 hour.⁸⁷ Temperatures of 85° to 95°C (185°F–203°F) for 1 minute are required for complete inactivation of HAV in foods such as shellfish.^{87,257} HAV is also completely inactivated by formalin (0.02% at 37°C [98.6°F] for 72 hours) but appears to be relatively resistant to free chlorine, especially when the virus is associated with organic matter.^{235,339} For general-purpose disinfection, a 1:100 dilution of 5% sodium hypochlorite (i.e., household bleach) in tap water inactivates HAV in most situations.^{61,130,131}

EPIDEMIOLOGY

Routes of Transmission

Routes of HAV transmission are determined by the timing and location of virus replication, circulation, and excretion during infection. HAV replicates in the liver, is excreted in bile, and is found in highest concentration in stool (up to 10^8 infectious particles per milliliter).³⁶³ The highest concentration in stool occurs during the 2-week period before jaundice develops or liver enzymes become elevated, followed by a rapid decline after jaundice appears (Fig. 168.2).^{133,346,363} Children and infants may shed HAV for longer periods than adults. Through the use of polymerase chain reaction (PCR) platforms to amplify viral nucleic acid, HAV RNA has been detected in the stool of infected neonates for as long as 6 months after infection, and some studies have shown excretion in older children and adults 1 to 3 months after the onset of clinical illness.^{176,318,420} Chronic shedding of HAV does not occur, although virus may be detectable in stool during relapsing illness (see the section on [relapsing hepatitis A](#)).³⁴⁵ Viremia occurs during the prodromal stage of infection and extends through the period of liver transaminase elevation (Fig. 168.3), with serum viral load several orders of magnitude lower than those in stool.^{42,76,208,222,225} In experimentally infected animals, HAV can be detected in saliva during periods of peak excretion in stool.⁷⁶ HAV also has been detected in the saliva of infected humans with concurrent HAV viremia through HAV RNA with identical serum and saliva sequences.²³³ This method is recommended for investigation of outbreaks.^{6,7} The saliva as an extrahepatic site of early HAV replication could create a potential risk for saliva-transmitted infection.⁵

Detection of HAV antigen in stool by enzyme immunoassay or detection of HAV RNA in serum or stool by PCR does not demonstrate that an infected person is infectious, because these assays may detect defective as well as infectious viral particles. HAV RNA may be detected in stool for months, beyond the period of infectivity. Data from epidemiologic studies suggest that peak infectivity occurs during the 2 weeks before the onset of symptoms until 1 to 2 weeks after the onset of jaundice. Fecal excretion of HAV may persist longer in children and in immunocompromised persons than in otherwise healthy adults. The development of the nucleic acid amplification by immunocapture reverse transcription PCR (RT-PCR) allowed for determination of viral infectivity by direct RT-PCR on virus captured by monoclonal antibody in the reaction tube.^{45,191} Immunocapture RT-PCR is useful to assess the infectivity of human enteric viral pathogens in the environment to aid in monitoring of water and food quality and for treatment processes.^{184,316}

Not surprisingly, HAV transmission occurs primarily by the fecal-oral route, usually by person-to-person transmission in households and extended-family settings and between sexual contacts.³⁵² Person-to-person transmission results in high rates of infection in young children in developing countries and has been the predominant mode of transmission

in the United States, particularly during community-wide outbreaks, as well as in outbreaks in childcare centers.^{25,27,37} HAV in feces has been shown to be infectious even after being dried and stored for 1 month, and extremely stable in the environment as previously discussed.^{247,87,246,247,294} Fecal contamination of food or water can result in common-source outbreaks. HAV has been transmitted by transfusion, but such transmission occurs rarely because the blood donation must occur during the early prodromal stage of the disease or from an asymptomatic person who is viremic.^{221,224} In the United States, PCR is applied to screening of source plasma used for the manufacture of plasma-derived products. These assays are sufficiently sensitive to remove most units that have HAV, and serosurveillance for HAV infections among recipients receiving blood products in the United States indicates that HAV infections are now rare.^{50,57}

The risk for transmission to newborns by pregnant women with HAV appears to be low, although data are scarce.^{71,310} Most infants born to mothers with HAV infection were not affected and had normal antibody and transaminase levels.^{262,327,371} A couple case reports have described vertical HAV transmission associated with jaundice and raised liver enzymes during the first weeks of life with uneventful improvement.^{124,310} Newborns who acquire HAV infection perinatally or from a transfusion usually are asymptomatic, and the infection is detected by the development of hepatitis A in hospital staff or other persons having contact with the infant.^{318,400} Two published case reports have described intrauterine transmission of HAV during the first trimester that resulted in fetal meconium peritonitis.^{218,248} After delivery, both infants were found to have a perforated ileum. Another study in Korea of 12 pregnant women with HAV included 1 case of fetal ascites and intraabdominal calcification suggestive of meconium peritonitis which spontaneously resolved in serial sonographic imaging, and 1 case of confirmed vertical transmission in 2009.⁷¹

Although mothers infected with HAV can have anti-HAV immunoglobulin (Ig)M and IgG antibodies and HAV RNA in their breast milk,^{90,96} transmission by breast milk has not been demonstrated.⁹⁶

Patterns of Disease Worldwide

Worldwide, the endemicity of HAV infection differs markedly among and within countries (Fig. 168.4).¹⁸² Patterns of HAV infection can be differentiated, each being characterized by distinct age-specific profiles of prevalence of antibody to HAV (anti-HAV), incidence of hepatitis A, and prevailing environmental (hygienic and sanitary) and socioeconomic conditions.^{23,27,157,159,181,182}

In areas with a high endemic pattern of infection, represented by the least developed countries (i.e., parts of Africa, Asia, and Central and South America), poor socioeconomic conditions allow HAV to spread readily (see Fig. 168.4). Most persons are infected as young children, and essentially the entire population is infected before reaching adolescence, as demonstrated by the age-specific prevalence of anti-HAV (Fig. 168.5).^{22,84,181,333,377} Because virtually all HAV infections occur in age groups in which asymptomatic infection predominates, reported disease rates may be low and outbreaks rare.

In areas of intermediate endemicity, HAV is not transmitted as readily because of better sanitary and living conditions, and the predominant age at infection is older than that in highly endemic areas.^{73,181} Paradoxically, the overall incidence and average age of reported cases often increase because high levels of virus circulate in a population that includes many susceptible older children, adolescents, and young adults, in whom symptoms are likely to develop with HAV infection.¹⁵⁵ Large common-source outbreaks also can occur because of the relatively high rate of virus transmission and the large number of susceptible persons, especially among those of higher socioeconomic levels. Such an outbreak occurred in Shanghai in the late 1980s, with more than 300,000 cases associated with the consumption of contaminated clams.¹⁶⁰ Nonetheless, person-to-person transmission in community-wide epidemics continues to account for much of the disease in these countries.³⁹¹

Considerable hepatitis A-related morbidity and associated costs can occur. A study at a tertiary care referral hospital in Karachi, Pakistan, identified 2735 patients younger than 15 years with confirmed hepatitis A during a 9-year period (1991–98). Of the 2735 patients, 232 were

FIG. 168.3 Immunologic, virologic, and biochemical events during the course of a typical hepatitis A virus (HAV) infection. ALT, Alanine transaminase; IgG, immunoglobulin G; IgM, immunoglobulin M.

FIG. 168.5 Distinct age-specific profiles of prevalence of antibody to hepatitis A virus (anti-HAV).

admitted to the hospital, and 30 patients (1%) developed progressive hepatic dysfunction and liver failure.³²⁹ In one Korean hospital, 304 patients older than 18 years were admitted from 2009 to 2011 with acute hepatitis A. Of those 304 patients, 18 (5.9%) progressed to acute liver failure, eight (2.6%) of whom died or underwent liver transplantation.³⁴⁰

In most areas of North America and Western Europe, sanitary and hygienic conditions are such that the endemicity of HAV infection is low. Relatively fewer children are infected, and disease often occurs in the context of community-wide and childcare-center outbreaks and occasionally as common-source outbreaks.^{26,27,149,302,330,331,366} In some regions (e.g., Scandinavia), the endemicity of HAV infection is very low and disease occurs almost exclusively in defined risk groups, such as travelers returning from areas where HAV infection is endemic or illicit drug users.⁴⁰

Changes have occurred in the epidemiologic trends and patterns of hepatitis A infection around the world related to vaccine A implementation, socioeconomic progress, and improvement in hygiene measures.^{182,196,210,216,214,260,378}

Systematic review and meta-analysis of published data using IgG anti-HAV seroprevalence data between 1990 and 2005 from different world regions indicated that high-income regions (i.e., Western Europe, Australia, New Zealand, Canada, the United States, Japan, the Republic of Korea, and Singapore) remain as having very low HAV endemicity levels and a high proportion of susceptible adults. The low-income regions (i.e., sub-Saharan Africa and parts of South Asia) still present high endemicity levels and almost no susceptible adolescents and adults, and most middle-income regions (i.e., Asia, Latina America, Eastern

Europe, and the Middle East) demonstrated a mix of intermediate and low endemicity levels.¹⁸²

Patterns of Disease in the United States

The epidemiology of hepatitis A in the United States has been altered profoundly by the introduction of hepatitis A vaccines, with a significant reduction as a vaccine-preventable infectious disease (Fig. 168.6A). Rates have declined sharply since the mid-1990s. The rate of HAV disease was less than one case per 100,000 population in all age groups starting in 2009.²⁶⁴ In 2010, 1670 cases were reported to the Centers for Disease Control and Prevention (CDC), representing a 94% decline in contrast to rates from 1990 to 1997 and significantly lower than previous incidence nadirs.^{64,65,67,68} Numbers of acute cases reported to CDC further decreased to 1239 in 2014. However, national surveillance systems collect data on symptomatic cases, and incidence models indicate that most infections are not symptomatic. One such analysis estimated that an average of 271,000 infections occurred per year during 1980 to 1999—10.4 times the reported number of symptomatic cases.¹² With use of similar modeling methodology, an estimated 17,000 infections occurred in 2010 (see Fig. 168.6B).^{55,66}

Variation by Age and Race or Ethnicity

Historically, the highest hepatitis A rates were reported among children 5 to 14 years of age, with approximately one third of cases occurring in children younger than 15 years.⁶² Because many young children have unrecognized or asymptomatic infection, they also are likely to represent a major reservoir for HAV transmission. Incidence models indicated that during the 1980s and 1990s, more than half of HAV infections occurred among children younger than 10 years, most of whom were younger than 4 years.¹² Since the mid-1990s, decreases in rates among children have been greater than among adults, and the proportion of cases among children dropped from 35% in the prevaccine era to 19% in 2003.³⁹⁹

From 2002 to 2010, rates were similar and low among persons in all age groups (<1.0 cases/100,000 population). In 2010, the range was from 0.23 to 0.74 cases per 100,000 population.^{64,65,67,68} The highest rates were for persons 15 to 24 years of age (0.74 cases per 100,000 population) and the lowest rates were among children younger than 9 years (0.3 cases/100,000 population).^{64,67} Since then, the percentage of patients with acute hepatitis A in the United States who were 0 to 19 years of age has steadily decreased to 11.10% in 2013, with the highest percentage continuing to be the 20- to 59-year age group (65.26%).^{230,231}

Before the use of hepatitis A vaccine, rates among Native Americans and Alaska Natives were more than 10 times higher than other racial and ethnic groups, and rates among Hispanics were approximately three

Available at: <https://www.cdc.gov/hepatitis/statistics/2010surveillance/slide2.1.htm>.)

times higher than among non-Hispanics. These disparities have lessened or disappeared in the era of routine childhood vaccination, with rates among Hispanics in 2003 dropping to approximately twice those among non-Hispanics (86% decline in contrast to 1990–97); rates among Native Americans and Alaska Natives were the same as or lower than those among other ethnic groups.³⁹⁹ In 2010, the rate for hepatitis A among Hispanics was 0.7 cases per 100,000 population, the lowest rate ever reported for this group.²⁶⁴ Rates among Native Americans and Alaska Natives in 2010 were the lowest ever recorded (0.2/100,000 population) and the same as or lower than other ethnic groups.^{64,67}

Seroprevalence of antibody to HAV (anti-HAV) in the population reflects immunity to either previous infection or vaccination. As determined by the National Health and Nutrition Examination Survey (NHANES), the overall seroprevalence of anti-HAV in the United States was 34.9% from 1999 to 2006.^{199,201} HAV seroprevalence among children has increased from 8% in 1988–94 to 35.3% in 2007–08, reflecting increased immunization of children and others.²⁵³ For US-born children 6 to 19 years of age, the strongest factor associated with seroprevalence was residence in vaccinating states. Among US-born adults aged older than 19 years, the overall age-adjusted seroprevalence of anti-HAV was 29.9% during 1999–2006, which was not significantly different from the seroprevalence during 1988–94.^{199,201} Among US-born adults 40 years of age and older, HAV antibody prevalence decreased from 1988–94

to 2003–06, which may reflect lower rates of infection secondary to higher rates of immunization among younger age groups.²⁵³ The decrease in seroprevalence in the adult population reflects the replacement of adults who were exposed naturally to HAV in the past by an adult population who were neither vaccinated nor previously exposed.¹⁶⁷

Geographic Variation

Analyses of national surveillance data collected during the 1980s and 1990s showed striking regional variation in the incidence of hepatitis A. The national average incidence was approximately 10 cases per 100,000 persons per year during 1987 to 1997, with the highest rates and almost all cases consistently occurring in a limited number of states and counties concentrated in the western and southwestern United States.^{54,63} Approximately two thirds of cases were reported from the 17 states with the highest rates, even though only one third of US residents lived in these states. With the implementation of routine vaccination of children in these states in 1999, rates equalized across the country,³⁹⁹ with significantly greater reductions in incidence in areas where vaccination was recommended.^{264,105,322,399}

HAV infection rates are now the lowest ever reported and similar in all regions. The rate of acute hepatitis A declined from 1.5 cases per 100,000 population to 0.54 per 100,000 population from 2005 to 2010.^{64,67}

In 2010, the case rate ranged from 0.1 case per 100,000 population (Arkansas, Mississippi, and South Dakota) to 1.0 case per 100,000 population (Arizona).^{65,68}

Potential Sources of Infection

The distribution of potential HAV exposures among cases for which information regarding exposures is available has changed in the vaccination era. The proportion of cases attributable to household or sexual contact with a person who has hepatitis A has declined as routine hepatitis A vaccination of children has increased, from 15% to 25% to 5.6% to 7.3% of reported cases in 2009 and 2010.^{56–58,60,64,65,67,68} The number of international travel–associated cases has remained approximately the same, but as overall incidence declined, the proportion of cases attributable to this exposure has risen to 14% to 15% reported in 2009–10.^{64,65,67,68} In sites conducting enhanced hepatitis surveillance during 2005–07 as part of the Emerging Infection Program of the CDC, the most frequent (46%) potential source of infection among persons reported with HAV disease was travel outside of the United States and Canada. These cases mostly reflected persons who traveled, but also included some who were exposed to a traveler but did not travel themselves.²⁰⁰ As in previous years, most travel-related cases (85%) were associated with travel to Mexico, Central America, and South America.^{200,333}

Recognized foodborne outbreaks account for a small proportion of cases in most years (3–5%), but large outbreaks such as those associated with contaminated green onions in 2003 have increased the proportion of cases associated with food in some years to as high as 16%.^{10,56–58,60,404,406} In 2010, the linkage to an outbreak could be determined in only 10% of the reported cases for which this information was available.^{65,68}

Cyclic outbreaks occur among men who have sex with men (MSM) and users of injecting and noninjecting drugs; during outbreak years, this exposure can account for 10% to 15% of nationally reported cases.^{58,60,83,142,162,171,323}

In 2010, only 5% of the case reports with information available about sexual practices indicated sex with another man and only 2% reported use of injection drugs.^{65,68} Nearly 50% of patients with hepatitis A do not have a recognized source of infection.^{57,58,60,64,65,67,68}

Community-Wide Epidemic

Historically, most cases of hepatitis A in the United States occurred in the context of community-wide epidemics, during which infection is transmitted from person to person in households and extended-family settings.²⁶ Once initiated, these epidemics often persisted for several years and proved difficult to control^{289,336,337} even when attempts were made to vaccinate some portion of the population rapidly.^{16,86} Children played an important role in HAV transmission during these epidemics. During community-wide outbreaks, serologic studies of members of households with an adult case and no identified source found that 25% to 40% of contacts younger than 6 years had serologic evidence of

having had recent HAV infection.^{313,352} In one of these studies, 52% of households of adults without an identified source of infection included a child younger than 6 years, and the presence of a young child was associated with household transmission of HAV.³⁵² In this study, transmission chains were identified involving as many as six generations and more than 20 cases. With the advent of routine vaccination of children, community-wide outbreaks have largely ceased. Community-wide outbreaks that have been sustained by transmission among adults in high-risk groups continue to be identified, and novel strategies to provide vaccination in settings such as jails have had some success.^{56,58,267,279,368,395}

Epidemiology of Hepatitis A in Specific Settings

Childcare Centers

The role of children with asymptomatic infection has been recognized in outbreaks in childcare centers since the 1970s.³³⁰⁻³³² Because infection in children usually is mild or asymptomatic, these outbreaks often are not recognized until adult contacts (usually parents) become ill.^{158,159} Outbreaks rarely occur in centers that do not have children in diapers and occur more commonly in larger centers.^{158,159} Both poor hygiene in these children and the need for staff to handle and change diapers contribute to spread. Despite the occurrence of outbreaks when HAV is introduced into a childcare center, studies of childcare center employees do not show a significantly increased prevalence of HAV infection in contrast to control populations.^{140,180} On occasion, outbreaks in childcare centers can be the source of more extensive transmission within a community.^{104,157,158,387} Hepatitis A outbreaks within childcare centers have become unusual events in recent years, as routine vaccination of all young children is the standard.

Other Groups and Settings

Hepatitis A cases in school-age children usually reflect disease that has been acquired in the community. However, multiple cases among children within a school may indicate a common-source outbreak.¹⁷² Historically, HAV infection was endemic in institutions for the developmentally disabled; however, with smaller facilities and improved conditions, the incidence and prevalence of infection have decreased, and outbreaks rarely are reported in the United States.³⁵⁷

During the past 2 decades, outbreaks have been reported with increasing frequency in illicit drug users in North America, Australia, and Europe.^{52,162,171,173,279,323,337,368,395} In the United States, these frequently involve users of injected and noninjected methamphetamine, who may account for as many as 30% of reported cases in these communities during outbreaks.^{26,171,173,267,395} Cross-sectional serologic surveys have demonstrated that injection drug users have a higher prevalence of anti-HAV than the general US population.^{178,393} More recent survey of 520 injection drug users age 18 to 40 years in San Diego from 2009 to 2010 found that 63% had no detectable anti-HAV antibodies,⁷⁸ suggesting that more aggressive implementation of the hepatitis A vaccine program is needed in this high-risk group.

Transmission among injection drug users probably occurs through both percutaneous and fecal-oral routes.¹⁷³

Hepatitis A outbreaks in MSM have been reported frequently, most recently in urban areas in the United States, Canada, Europe, and Australia.^{38,50,83,142,328,355,373,374} These outbreaks may occur in the context of an outbreak in the larger community.²⁶ Some studies conducted during outbreaks and seroprevalence surveys among MSM identified specific sex practices associated with illness, whereas others have not demonstrated such associations.^{30,83,85,165,192,393}

Transfusion-related hepatitis A rarely occurs because HAV does not result in chronic infection and blood donors are screened for elevated transaminase levels. Currently, nucleic acid amplification tests also are used to screen source plasma used in the manufacture of plasma-derived products. However, during the mid-1990s, outbreaks were reported in Europe and the United States in patients who received factor VIII and factor IX concentrates prepared by solvent-detergent treatment to inactivate lipid-containing viruses.^{238,349} HAV is resistant to solvent-detergent treatment, and contamination presumably occurred from plasma donors with hepatitis A who donated during the incubation period. The risk for acquiring infection in patients with hemophilia is not known, although data from one serologic survey of hemophiliac

patients suggested that they might be at increased risk for acquisition of HAV infection.²³⁴ However, no HAV infections attributed to blood products were identified in an analysis of serosurveillance data collected from 140 hemophilia treatment centers in the United States between 1998 and 2002, suggesting that improved viral inactivation procedures, donor screening, and increased hepatitis A vaccine coverage among clotting factor recipients can reduce the risk for transmission of HAV to recipients of clotting factors.^{50,57} Transmission related to blood transfusions has resulted in nosocomial outbreaks in neonatal intensive care units.^{198,277,318} Hepatitis A has been reported in adult cancer patients treated with lymphocytes that apparently were incubated in serum from a donor with HAV infection, although the patient source was not identified.⁴⁰²

Nosocomial transmission from adult patients to health care workers has often been associated with fecal incontinence of the patient.^{153,287,288} Such transmission is a rare event, however, because most patients with hepatitis A are hospitalized after the onset of jaundice, when infectivity is low.^{130,131,346} Health care workers have not been found to have an increased prevalence of anti-HAV in contrast to control populations in serologic surveys conducted in the United States.¹⁴⁸

Persons from developed countries who travel to developing countries with a high, transitional, or intermediate endemicity of HAV infection are at substantial risk for acquiring hepatitis A (see Fig. 168.4).^{182,333,354}

Hepatitis A infection is one of the most common vaccine-preventable infections acquired during travel.³³³ A more recent study of Swiss travelers estimated the risk to be six to 30 cases per 100,000 person-months of stay in developing countries among persons who did not receive immunoglobulin or vaccine before departure.²⁶⁶ The risk is higher among travelers staying in areas with poor hygienic conditions,²¹¹ it varies according to the region and the length of stay, and it appears to be increased even among travelers who reported staying in urban areas or luxury hotels.^{333,354} In some European countries, returning international travelers with hepatitis A account for a substantial proportion of reported cases (16–40%).^{72,410} In the United States, the proportion of cases attributed to recent international travel has increased from 5% to 15%.^{64,65,67,68}

The potential for new foodborne outbreaks around the world has been enhanced with the world globalization by importation of food products from countries where hepatitis A remains endemic to countries with low endemicity. This has been nicely demonstrated during recent outbreak investigations of hepatitis A infection, including the multistate outbreak associated with semidried tomatoes in Australia during 2009¹¹³ and similar outbreaks in the Netherlands^{296,297} and France during 2010.¹⁴⁶

Foodborne hepatitis A outbreaks are now recognized relatively infrequently in the United States and are associated most commonly with contamination of food during preparation by a food handler with HAV infection. However, persons who work as food handlers are not at increased risk for acquiring hepatitis A because of their occupation. Food contaminated before retail distribution, such as lettuce or fruits contaminated at the growing or processing stage, has been recognized as the source of hepatitis A outbreaks.^{10,101,103,172,275,309,317,406} Outbreaks related to contaminated shellfish, commonly noted in the past,^{103,108,282,301} have become increasingly uncommon.³¹ After the large multistate outbreaks linked to oysters in 2005,^{31,101,404,406} another large outbreak of occurred United States in 2013 associated with frozen pomegranate arils imported from Turkey. A total of 165 people from 10 states became ill with hepatitis A genotype IB, 69 (42%) of whom required hospitalization, but no deaths were reported.⁷⁹ Waterborne transmission of HAV is now rare in the United States; earlier outbreaks were linked to sewage contamination or inadequate treatment of water.^{29,36,41,46,98,143,235,398} In 2014, 13 (2.6%) of 500 case reports linked to an outbreak indicated exposure that may have been linked to a common-source foodborne or waterborne outbreak.^{66,69,264}

Control of food outbreaks usually requires intensive public health effort.⁹³ HAV foodborne disease investigation with direct food testing through HAV RNA molecular techniques has made the recovery of implicated food faster and more efficient.³¹ Molecular epidemiology through sequencing of outbreak strains has been demonstrated to be an excellent tool for the investigation of HAV infection outbreaks within the United States and European countries.^{31,113,146,167,296,374}

PATHOLOGY AND PATHOGENESIS

Pathology

The light microscopic findings in acute hepatitis A, which include inflammatory cell infiltration, hepatocellular necrosis, and liver cell regeneration, are common to all forms of acute viral hepatitis. These histologic findings vary with the stage and severity of hepatitis. Early biopsy specimens generally show portal infiltration by lymphocytes, plasma cells, and macrophages positive for periodic acid–Schiff.^{109,365} Spotty or focal necrosis, as evidenced by ballooning degeneration, shrinkage, and fragmentation of hepatocytes, is seen commonly.¹⁰⁹ HAV antigen is found primarily in the cytoplasm of hepatocytes, but it also can be found in liver macrophages. However, because HAV infection is self-limited and does not result in chronic liver disease, liver biopsy rarely is indicated (see the discussion on [treatment](#)).

Differences have been noted in light microscopic findings of hepatitis A and other forms of viral hepatitis, particularly hepatitis B. In addition to degeneration of hepatocytes in the perivenular area, periportal inflammation and destruction of hepatocytes adjacent to the portal area may be more pronounced than in hepatitis B.^{1,283,365} Findings in some patients, including extension of the inflammatory infiltration from the periportal area into the hepatic parenchyma and disruption of the limiting plate, may be difficult to distinguish from those of chronic hepatitis.^{1,109} Cholestasis can be more prominent than in hepatitis B.³²⁴

The histologic findings in fulminant hepatitis A are indistinguishable from those in other forms of fulminant viral hepatitis. Examination of pathologic specimens shows massive hepatic necrosis, abnormal architecture of surviving hepatocytes, and a diffuse inflammatory response.^{203,204} Viral antigen can be found in pathologic specimens.

Pathogenesis

The mechanism by which HAV crosses gastrointestinal epithelium and infects liver cells has not been completely established. Previous studies have shown that HAV-IgA complex can translocate across epithelial cells and that HAV-IgA complexes are taken up by hepatocytes through the asialoglycoprotein receptor.^{114,115} In this model of HAV infection, virus would first infect gastrointestinal cells and then be transported into the enterohepatic circulation as part of an HAV-IgA complex, with subsequent selective uptake by hepatocytes. HAV is able to bind to human cells through a specific cellular receptor inserted into the plasma membrane, and DNA that encodes this receptor (huhavcr-1) has been identified in many human tissues.¹³² HAVCR-1 was first discovered as the cellular receptor for HAV (HAVcr-1) in African green monkeys in 1996.¹⁹⁰ This cellular receptor is a member of the T-cell immunoglobulin mucin (TIM, also known as TIM-1) gene family. It appears to regulate the size and effector functions of T cells and also might play a role in the development of atopy.²⁴⁹ The relationship of TIM1 and atopy with HAV exposure is important, and various epidemiologic studies around the world have shown lower prevalence of allergy and asthma among the HAV-seropositive individuals in contrast to HAV-seronegative individuals.^{244,245} Immunoglobulin (Ig)A is a natural ligand of HAVCR-1, and the association of IgA with HAVCR1 enhances virus receptor activity with synergistic effect in virus-receptor interactions.³⁶¹

HOST INNATE AND ADAPTIVE IMMUNE RESPONSES

Cellular Immune Response

Unlike other picornaviruses, infection of cultured cells with wild-type HAV has no cytopathic effect.³⁹⁶ The general assumption is that HAV infection also is noncytopathic in vivo, and therefore the cytopathic changes in the liver associated with hepatitis A are immune mediated. HAV is able to suppress interferon (IFN)- β gene expression in the initial stages of infection, which might facilitate prolonged viral production and infection of neighboring cells.¹³⁴ This could be explained in part by a disruption in the signaling through the toll-like receptor 3 pathway.^{242,306} A recent research study demonstrated that the interaction between HAV and its receptor HAVCR1 inhibits CD4 T-cell regulatory cell function, resulting in an immune imbalance allowing viral expansion

with limited hepatocellular damage during the early phase of infection, which is characteristic of HAV infection.²³⁷ Symptoms and biochemical evidence of liver injury do not occur at the time of maximum virus replication and fecal shedding (during the late incubation period). Rather, liver injury is associated closely with viral clearance. CD8⁺, class I-dependent, cytotoxic, and virus-specific T cells that are capable of producing IFN- γ are present in the circulation and the liver.^{139,380} Additional inflammatory cells, recruited to the site of infection by IFN- γ and other cytokines secreted by CD8⁺ cells, may be responsible for much of the liver injury. Complement has been shown to bind to HAV capsid proteins, and serum complement levels drop during infection, but whether complement-mediated cellular injury occurs is unclear.²⁴¹ The mechanism by which infection is resolved remains uncertain.

Humoral Immune Response

Unlike hepatitis C, the adaptive immune response to HAV is robust and extremely effective in eliminating the virus. Neutralizing antibodies to the virus (anti-HAV) generally appear in the serum concurrent with the earliest evidence of serum transaminase elevation and hepatocellular injury.

Antibodies directed against conformational epitopes displayed on intact virions as well as empty viral capsids are produced during the later stages of infection (see the earlier section on [genomic organization and genetic variation](#)). Virus-specific IgM and IgG and IgA antibodies are present in serum; IgM anti-HAV generally can be detected at the onset of symptoms (see [Fig. 168.3](#)).²⁴²

CLINICAL MANIFESTATIONS

Similar to other forms of viral hepatitis, the clinical manifestations of HAV infection are variable and range from asymptomatic anicteric infection to symptoms of acute hepatitis, including fever, malaise, anorexia, nausea, vomiting, right upper quadrant pain, and jaundice. The likelihood of having symptomatic HAV infection and the severity of the illness are related to the age of the patient. In early childhood, infection usually is asymptomatic, whereas infection in adulthood generally is accompanied by symptoms. The diagnosis of hepatitis A must be confirmed by serologic testing because no constellation of symptoms is pathognomonic of the disease.

Incubation Period

The average incubation period is 28 to 30 days but can range from 15 to 50 days.²⁰⁶ The average incubation period has been reported to be shorter in patients who acquired HAV infection by parenteral transmission from contaminated blood products and in chimpanzees infected parenterally than in those infected orogastrically.^{241,338}

Spectrum of Illness

HAV infection, confirmed by the detection of IgM anti-HAV in serum, can be inapparent (asymptomatic, with no elevation in serum transaminase levels), subclinical (asymptomatic, with elevation of serum transaminase levels), or clinically evident (with symptoms). Specific symptoms of liver dysfunction include jaundice and dark urine caused by hyperbilirubinemia. However, symptomatic hepatitis A without jaundice (anicteric) does occur. Nonspecific symptoms of acute hepatitis A can include fever, myalgia, anorexia, nausea, right upper quadrant pain or discomfort, diarrhea, and pruritus.

Many acute HAV infections, particularly subclinical and anicteric infection, are not recognized.^{352,418} The frequency of symptoms with acute infection is influenced strongly by age. Children are less likely than adults to have symptomatic infection, and jaundice rarely occurs in children younger than 6 years.¹⁵¹ In one report describing outbreaks in several daycare centers, the proportion of infected children without symptoms was 84% in children younger than 3 years, 50% in children 3 to 4 years of age, and 20% in children 5 years or older.^{158,159} Symptoms develop in most adults with acute infection. In a study of two outbreaks among young adult US military personnel, symptoms developed in 76% to 97% of infected persons, and approximately 55% were icteric.²¹³

CLINICAL SIGNS AND SYMPTOMS

In an individual patient, the clinical symptoms of acute hepatitis A are indistinguishable from those caused by other forms of viral hepatitis. Particularly in older children and adults, the onset of illness often is quite abrupt and may consist of fever, myalgia, anorexia, malaise, nausea, intermittent dull abdominal pain, and vomiting. Fever (temperature rarely higher than 38.9°C [102°F]) and headache occur more frequently than in other forms of acute viral hepatitis.³⁵⁸ Pediatric patients may have diarrhea or, less commonly, upper respiratory tract symptoms such as cough, sore throat, and runny nose, and the diagnosis of hepatitis A might not be considered in children with predominantly respiratory or gastrointestinal symptoms and transient fever without the typical malaise, fatigue, and anorexia.^{138,219,225} Dark urine followed by jaundice and light-colored stool, if present, will appear within a few days to a week after onset of the prodromal symptoms.^{28,156,213,219,225} When this icteric phase begins, symptoms often resolve and appetite returns in young children, but older children and adult patients may experience a transient worsening in the prodromal symptoms of anorexia, malaise, and weakness.^{205,263}

In addition to jaundice and scleral icterus, physical findings may include mild hepatomegaly and tenderness, but severe tenderness suggests other diagnoses. The spleen may be palpable in 10% to 20% of patients, and posterior cervical adenopathy may be present.^{75,213,372} Pleural effusions have been reported to occur, do not appear to be associated with more severe disease, and resolve spontaneously.⁴ Ascites, peripheral edema, and findings indicative of hepatic encephalopathy suggest the presence of a more severe form of hepatitis but are rare (see the discussion on [atypical clinical manifestations and complications of hepatitis A](#)). Ultrasonographic findings in children with uncomplicated hepatitis A have included edema or thickening of the gallbladder wall, abdominal lymphadenopathy, and, less commonly, transient ascites and pancreatic abnormalities.^{75,197}

The symptoms of hepatitis A last for several weeks on average and usually not longer than 2 months.^{203,204} Prolonged or relapsing hepatitis A can occur (see the discussion on [relapsing hepatitis A](#)) and, in the case of prolonged hepatitis A, may be associated with genetic markers for autoimmune hepatitis.¹²⁸

Laboratory Abnormalities

As in other forms of viral hepatitis, during HAV infection, inflammation of the liver is accompanied by abnormalities in serum hepatic enzymes, with increases in serum aspartate transaminase (AST), alkaline phosphatase, and γ -glutamyltranspeptidase (GGTP) levels. Elevations of serum ALT and AST occur most consistently and may precede the appearance of symptoms by a week or more (see [Fig. 168.3](#)). Peak levels generally occur 3 to 10 days after the onset of symptoms and are between 200 and 5000 IU but can reach as high as 20,000 IU. The level of ALT usually is higher than that of AST because the inflammatory response is destructive, particularly to the plasma membrane, in acute viral hepatitis. ALT is found in the cytosol of the plasma membrane, whereas AST is located mainly in cell mitochondria.¹⁵⁶

Serum bilirubin levels, although frequently elevated, usually remain below 10 mg/dL and peak 1 to 2 weeks after illness begins. Higher levels can be seen in some patients, especially when HAV infection is complicated by cholestasis (see the section on [cholestatic hepatitis A](#)). Alkaline phosphatase is usually only mildly elevated, rarely reaching more than 2 or 3 times the normal level. GGTP levels generally are 3 to 10 times the upper limit of normal. Serum immunoglobulin levels often are elevated, and IgM levels frequently are higher than those in acute hepatitis B and non-A, non-B hepatitis, but not diagnostic.⁴²² Coagulopathy or elevated prothrombin time (PT)/international normalized ratio (INR) are rare. A prolongation of these labs are generally associated with severe liver damage and a prognostic indicator for the development of fulminant hepatitis.⁴¹⁴

Patients with acute HAV infection usually have a mild lymphocytosis with occasional atypical mononuclear cells.²⁶³

Apart from patients who have relapsing or cholestatic hepatitis A (see the section on [atypical clinical manifestations and complications of hepatitis A](#)), serum bilirubin and transaminase levels usually

return to normal by 2 to 3 months after the onset of illness in most patients.^{203,204}

Diagnostic Tests

Because the pattern and magnitude of symptoms and the hepatic enzyme abnormalities of hepatitis A are not distinctive for hepatitis A, the diagnosis requires serologic detection of IgM anti-HAV along with demonstration of an acute onset of signs and symptoms of hepatitis and jaundice or elevated transaminase levels. Persons with signs and symptoms of hepatitis and an epidemiologic link to other confirmed cases are likely to have hepatitis A, even if no laboratory confirmation is available. Sensitive and specific radioimmunoassays or enzyme immunoassays show that virtually all patients have detectable IgM anti-HAV during the acute or early convalescent phase of HAV infection (see [Fig. 168.3](#)).²²⁷ A small proportion (3%) of patients tested within 3 days of the onset of symptoms may be IgM anti-HAV negative but become IgM anti-HAV positive within the initial 2 weeks of illness.²²⁷ During the first 4 to 8 weeks after the onset of symptoms, the titer of IgM anti-HAV in serum is high.¹⁶³ Antibody generally disappears within 6 months, although rarely it can be detected for 2 years or longer.^{111,163,202,227}

False-positive IgM anti-HAV test results among persons who have no other evidence of recent infection have been reported, suggesting a low positive predictive value when it is used to test asymptomatic persons with no known recent HAV exposures.^{54,58,59,63} IgM anti-HAV may be detectable for a longer time in patients with symptomatic illness than in those with asymptomatic infection.^{163,189,347}

IgG anti-HAV is present in low titer at or shortly after the onset of acute HAV infection, and the titer rises during the course of several weeks as the IgM anti-HAV titer falls (see [Fig. 168.3](#)). IgG anti-HAV remains detectable in serum for the lifetime of the individual and confers lasting protection against disease. Secretory IgA antibodies are detected in a minority of humans or primates with acute HAV infection but are unlikely to provide any significant protection against HAV infection.³⁵³ IgG anti-HAV is transferred passively across the placenta and declines to undetectable levels in most infants by the time they reach 12 to 15 months of age.^{25,26,228,229}

Commercially available enzyme immunoassays either detect total (IgG and IgM) antibody against HAV capsid proteins by using a competitive inhibition (blocking) format or detect IgM antibody to capsid proteins by using an IgM capture format.^{220,223} These assays do not measure the neutralizing antibodies responsible for biologic activity against HAV, but detection of total anti-HAV by conventional assays is correlated with the appearance of neutralizing antibodies.^{205,220,223} Neutralizing antibody can be detected by assays that measure inhibition of HAV in cell culture (i.e., radioimmunofocus inhibition test or plaque assay).^{11,88,220,223} Neutralizing antibodies elicited against one strain of HAV have been shown to have biologic activity against other HAV strains.^{220,223}

When tested in parallel with a World Health Organization anti-HAV reference reagent, the lower limit of detection of most commercially available assays is approximately 100 mIU/mL of anti-HAV.^{147,220,223} Although antibody concentrations achieved by passive or active immunization are known to provide protection against HAV infection, they are generally 10- to 100-fold lower than those produced after natural infection.^{220,223}

The lower limit of antibody necessary to provide protection against HAV infection is unknown. In vitro studies with cell culture–derived virus suggest that low levels of antibody (e.g., <20 mIU/mL) are neutralizing.^{220,223} Clinical trials that evaluated vaccine efficacy have not provided an estimate of the minimum protective antibody level because vaccine-induced levels of antibody have been very high and few infections have occurred in vaccines. Experimental studies in chimpanzees indicate that very low levels of passively transferred antibody (<10 mIU/mL) obtained from immunized individuals do not protect against infection but prevent clinical hepatitis and shedding of virus.³⁰⁵

PCR techniques using serum specimens have been useful in some clinical, epidemiologic, or environmental studies. Although HAV concentrations in stool decline quickly after illness onset, HAV RNA can be detected in most serum specimens that are collected within 4 to 6 weeks after onset of illness.⁴²

Atypical Clinical Manifestations and Complications of Hepatitis A

Box 168.1 lists the atypical clinical manifestations and complications of hepatitis A.

Relapsing Hepatitis A

Relapsing hepatitis is a relatively common manifestation of hepatitis A that occurs in approximately 10% of patients.³²⁵ One to 4 months after having the initial episode of acute hepatitis, these patients have a second episode; more than one relapse rarely occurs.^{152,325,370} Patients with relapsing hepatitis A have no distinctive clinical features of their first disease episode. After the first episode, most patients experience a significant improvement in symptoms and biochemical abnormalities. However, the frequency with which serum transaminase levels completely normalize during this period has been variable; in one report, normalization occurred in only one of seven patients with relapsing hepatitis A.³⁷⁰ The relapse episode of hepatitis rarely is more severe than the initial episode and is accompanied by elevated serum transaminase levels (typically to >1000 U/L) and persistence of IgM anti-HAV. Molecular studies have demonstrated the presence of HAV in stool and HAV RNA in serum during relapse, but whether patients are infectious is unknown.¹⁵² The illness usually lasts a total of 16 to 40 weeks and results in full recovery.^{152,325} Although the pathogenesis of relapsing hepatitis is unknown, it probably is immunologically mediated.³²⁵ Persistent HAV infection with a relapsing clinical course has been reported in patients after they have undergone liver transplantation for fulminant hepatitis A; HAV-specific genomic sequences have been identified in the grafts of these patients.^{127,414}

The IgA has been postulated as a carrier supporting hepatotropic transport of HAV, which may contribute to different clinical outcomes.¹¹⁶ Over a period of several weeks after infection, anti-HAV IgA is able to promote an enterohepatic cycling of HAV, resulting in continuous endogenous reinfection of the liver. A mouse model demonstrated that highly avid IgG antibodies, which are present in later times of the infection, can terminate the reinfection. The endogenous reinfections in the presence of a developing neutralizing immunity might contribute to prolonged, as well as relapsing, courses of HAV infections, and the IgA may act as a protracting factor.¹¹⁶

Fulminant Hepatitis A

In the United States, a relatively small proportion of all fulminant hepatitis is caused by hepatitis A.^{243,285,308,326,369} A prospective multicenter study conducted among 348 children with acute liver failure in the United States, Canada, and the United Kingdom found that only three cases (1%) could be attributed to hepatitis A.³⁵¹ However, 26% to 60%

of children with acute liver failure had hepatitis A in tertiary care center-based studies conducted in Turkey, India, Argentina, and Pakistan.^{15,18,21,329} In one Korean hospital, 304 patients more than 18 years of age were admitted from 2009 to 2011 with acute hepatitis A. Of those 304 patients, 18 (5.9%) progressed to liver failure, and of these, eight (2.6%) died or underwent liver transplantation.³⁴⁰ Between 1998 and 2005, 29 adults with HAV IgM-positive acute liver failure were enrolled in the Acute Liver Failure Study Group (ALFSG) in the United States. Acute HAV accounted for 3.1% of the patients enrolled. At 3 weeks of follow-up, 16 had spontaneously recovered (55%), nine underwent transplantation (31%), and four had died (14%). The proportion of HAV cases enrolled in the ALFSG significantly decreased from 5% to 0.8% between 1988 and 2005 ($P < .007$).³⁶⁴

Among patients hospitalized with hepatitis A, the case-fatality rate has been estimated to be 0.14%.²⁵² In the 1988 Shanghai epidemic that involved primarily adolescents and young adults, 47 deaths (0.015%) were recorded among the 310,746 diagnosed cases.⁸⁰ A national cohort study in Taiwan looking at hospital admissions related to HAV from 1997 to 2011 showed an overall mortality rate of 16.8 per 1000 hospitalizations. Male sex, age over 40 years, cirrhotic liver, and long length of stay are significant factors associated with death in HAV-hospitalized cases.⁷⁰ On the basis of national surveillance data in the United States, death occurs in 0.3% to 0.6% of persons with symptomatic hepatitis A, reaching 1.8% among those over 50 years of age.³³³ In 2013, nine (0.9%) cases of deaths related to HAV were reported to the CDC. None were reported in 2014.^{65,68,69}

Host factors reported to be associated with an increased risk for development of fulminant hepatitis include older age^{44,209,252,394,417} and underlying chronic liver disease.^{3,95,193,224,389,394,415,417} Reported findings among persons with fulminant disease include nucleotide or amino acid substitutions in the 5' untranslated region,¹⁴⁵ P2 region, and P3 region of the HAV genome.²⁷⁰ Viral factors such as substitution rate in the entire genome were not associated with acute liver failure in the 29 patients identified with HAV liver failure in the adult ALFSG from 1998 to 2004; however, a negative PCR (undetectable or very low viral load) was the single factor that correlated more significantly with more severity and worse outcomes.² This finding has been previously described in the literature and suggests that the excessive host response maybe a determining factor in the development of fulminant hepatitis A.³¹¹ An in-depth analysis conducted in India for a 5-year period concluded that higher CD8 T cells and coinfection with other viral hepatitis infections were more commonly associated with fulminant hepatitis; and, contrary to previous findings, higher viral load was also an important contributing factor.¹⁷⁰

Fulminant hepatitis A has no distinctive clinical features that distinguish it from fulminant hepatic failure of other causes. Within approximately 8 weeks of the onset of illness, symptoms of hepatic encephalopathy and marked prolongation of PT are noted in patients with no history of previous liver disease.²⁸¹ Complications can include cerebral edema, sepsis, gastrointestinal bleeding, and hypoglycemia. The prognosis of fulminant hepatitis A without transplantation is better than that of fulminant disease related to other viral causes, and 40% to 70% of patients can be expected to recover.^{150,280,326,369} In one hospital series, more rapid onset to liver failure after onset of jaundice was associated with improved outcome, and higher bilirubin concentration and more prolonged prothrombin time were associated with poor outcomes.⁹⁹

Extrahepatic Manifestations

During acute hepatitis A, transient rash and arthralgias occur in as many as 14% and 19% of patients, respectively, particularly during the prodromal period.^{150,370} Urticaria has been reported but occurs less frequently than in acute hepatitis B.¹¹⁰ Papular acrodermatitis of childhood, the Gianotti-Crosti syndrome, rarely occurs in the United States but has been reported elsewhere in association with HAV infection.³²⁰ The cutaneous lesions, which consist of nonpruritic, symmetric flat papules on the face, extremities, and buttocks, may persist for several weeks before spontaneously resolving.¹¹⁷

Other extrahepatic manifestations that occur chiefly in association with cholestatic or relapsing hepatitis A include cutaneous vasculitis

and cryoglobulinemia.^{94,174,175} The vasculitis, manifested as erythematous maculopapular lesions often affecting the lower extremities and buttocks and typically associated with purpura, appears as leukocytoclastic vasculitis and granular deposits of IgM anti-HAV and complement in blood vessel walls in skin biopsy specimens. Cryoglobulinemia includes cryoglobulins composed of IgG and IgM and IgM anti-HAV antibodies.^{94,174,175,325} These manifestations resolve spontaneously with resolution of the hepatitis.

In the absence of fulminant disease, neurologic syndromes have been observed only rarely in association with hepatitis A. Guillain-Barré syndrome has been reported to occur 3 days to 2 weeks after the onset of hepatitis A, as have myeloradiculopathy, vertigo, mononeuritis (cranial or peripheral nerve), meningoencephalitis, and exacerbation of multiple sclerosis.^{19,39,291,292,359} Renal complications, including acute renal failure, nephrotic syndrome, and acute glomerulonephritis, also rarely have been reported in children who did not have fulminant disease.^{17,100,183} Self-limited, mild pancreatitis likewise appears to occur.²⁵⁹ Reported hematologic complications include aplastic anemia and severe thrombocytopenia.^{125,236} Gestational complications, including premature rupture of membranes and placental separation, have been reported among pregnant women with acute hepatitis A, but infants born to these women were healthy otherwise.^{119,319}

Cholestatic Hepatitis A

Cholestatic hepatitis occurs in a small percentage of patients with hepatitis A. These patients are deeply icteric and may have pruritus, fatigue, fever, loose stools, anorexia, dark urine, and weight loss. In two reports of 10 patients with cholestatic hepatitis A, peak serum bilirubin levels generally were higher than 10 mg/dL, with some as high as 38 mg/dL, and remained elevated for 12 to 16 weeks.^{154,370} Serum transaminase levels declined but remained elevated during the period of cholestasis. In one of these reports, five patients had prolonged prothrombin times that normalized with the administration of vitamin K.¹⁵⁴

Cholestatic hepatitis A can be distinguished from obstructive jaundice by normal abdominal ultrasound findings. Conducting further invasive diagnostic procedures, such as liver biopsy or endoscopic retrograde cholangiopancreatography (ERCP), is not necessary in most cases.³²⁵

Hepatitis A Triggering Autoimmune Hepatitis

Several reports have described patients in whom hepatitis A is followed by type 1 autoimmune chronic hepatitis.^{307,370,388} Laboratory studies demonstrated a T-cell defect in these patients, suggesting a genetic predisposition to the development of autoimmune hepatitis that is “triggered” by HAV infection. These patients have required corticosteroid therapy, sometimes for long periods.

TREATMENT

Hepatitis A has no specific therapy, and because HAV infection is self limited and does not result in chronic infection or chronic liver disease, treatment generally is supportive with hydration and good nutrition. Hospitalization may be necessary for patients who are dehydrated from nausea and vomiting or who have fulminant hepatic failure. Because no conclusive data indicate that bed rest or inactivity influences the course of illness, no restriction of activity is necessary. Similarly, no specific diet is indicated, although many patients may have an intolerance to fatty foods during their illness. Medications, particularly those that have the potential to cause hepatic damage and those that are metabolized by the liver, including acetaminophen, should be used with caution. The half-life of these medications may be prolonged.

No evidence exists that exchange transfusions, plasmapheresis, or corticosteroids are effective.^{126,156} Liver transplantation is successful in the few who require it.^{164,343,369,393} Persistent HAV infection has been demonstrated in some transplant recipients, but whether it affects survival is unknown.^{118,127} Because survival rates of adult and pediatric patients are relatively high without transplantation and no single factor is predictive of a poor outcome, establishment of criteria for choosing candidates for transplantation has been difficult.^{150,281,369,386} Reported survival rates after transplantation in patients with fulminant hepatitis from all viral

causes range from 40% to 89%, depending on the severity of liver failure and other factors.^{215,217,369}

Investigators are exploring direct-acting antivirals (DAAs) as a treatment option for the treatment of acute hepatitis infections, including HAV 3C cysteine protease inhibitors and HAV-specific siRNAs. HAV 3C proteinases play an important role in the processing of the HAV polyprotein, and inhibitors of HAV 3C can result in the suppression of HAV replication.¹⁸⁸ Studies revealed that siRNAs against the HAV 2C- and 3D-coding regions inhibited HAV 2C and HAV 3D expression and that the combination of 2C-siRNAs and 3D-siRNAs strongly inhibited HAV replication.^{187,186} Exploration of DAAs for the treatment of HAV remains in the early stages of investigation in vitro and cell cultures. Human studies have yet to be performed.

PREVENTION

In addition to general measures of good personal hygiene, particularly handwashing; provision of safe drinking water; and proper disposal of sanitary waste, preexposure or postexposure immunization primarily with hepatitis A vaccine or with immunoglobulin can prevent the acquisition of hepatitis A.

Immunoglobulin

Immunoglobulin is a sterile solution of antibodies prepared by a serial cold ethanol precipitation procedure from pooled human plasma that has tested negative for hepatitis B surface antigen, antibody to human immunodeficiency virus (HIV), and antibody to hepatitis C virus.⁷⁷ When it is administered before exposure or within 2 weeks after exposure, immunoglobulin is more than 85% effective in preventing hepatitis A by passive transfer of anti-HAV.^{202,261,355} Whether immunoglobulin completely prevents infection or leads to asymptomatic infection and the development of persistent anti-HAV (passive-active immunity) probably is related to the amount of time that has elapsed between exposure and administration of immunoglobulin.^{219,225,355} Although in recent years immunoglobulin lots have had slightly lower titers of anti-HAV, probably because of a decreasing prevalence of previous HAV infection in plasma donors, no clinical or epidemiologic evidence of decreased efficacy has been reported.³⁶²

Hepatitis A immunoglobulin (IG) may be given instead of or in addition to hepatitis A vaccine to certain groups who are traveling to countries with high, transitional, or intermediate endemicity of HAV infection (see Fig. 168.4).^{54,63} Travelers who are at increased risk of severe or fatal hepatitis A infection, including adults older than 40 years of age (particularly adults 75 years and older), persons with chronic liver disease, those who are immunocompromised, and those who are planning to depart in 2 weeks or less should receive IG (0.02 mL/kg) at a separate anatomic injection site in addition to the standard initial dose of vaccine. IG is also indicated for travelers who are allergic to a vaccine component or who elect not to receive the vaccine, as well as for travelers younger than 12 months, as hepatitis A vaccine is not licensed in the United States for children in this age group (see the section on vaccines).^{54,63} Although hepatitis A often is asymptomatic in infants and young children, preexposure prophylaxis is indicated to prevent the rare severe cases and transmission to others after return from abroad.

For preexposure prophylaxis of travelers, the dose of IG is 0.02 mL/kg body weight if travel will be for less than 3 months. Because of the decay of passive immunity during the course of time, a dose of 0.06 mL/kg is necessary for persons who will be abroad for 3 to 5 months, and readministration every 5 months is necessary for extended trips. Hepatitis A vaccine, if it is not contraindicated, is a better choice for such persons and can be administered at any time prior to departure in healthy persons.

Aggressive use of vaccine immunoprophylaxis is indicated to control hepatitis A outbreaks^{409,300} in childcare centers in which hepatitis A is diagnosed in a child or employee^{54,61,63,330,331} and in other settings (e.g., hospitals and facilities for developmentally disabled persons) when outbreaks occur.^{55,60} When a food handler is identified with hepatitis A, postexposure prophylaxis should be administered to other food handlers at the establishment and, under limited circumstances, to patrons.^{49,54,63,135,136} Once cases are identified that are associated with a

food service establishment, it generally is too late to administer post-exposure prophylaxis to patrons because the 2-week postexposure period during which prophylaxis is effective will have passed.

Previously unvaccinated household or sexual contacts of patients with hepatitis A should receive postexposure prophylaxis. In the absence of postexposure prophylaxis, secondary attack rates of 15% to 30% have been reported in households, with higher rates of transmission occurring from infected young children than from infected adolescents and adults. Attack rates in food handlers are generally lower.²⁰¹

IG is usually used for postexposure prophylaxis in susceptible persons who are either children younger than 12 months or persons older than 40 years, immunocompromised persons, and persons with chronic liver disease.²⁰¹

For postexposure prophylaxis, 0.02 mL/kg body weight of IG is administered intramuscularly. For infants and young children, the injection can be administered in the anterolateral aspect of the thigh or the deltoid muscles; for older children and adolescents, the injection should be administered in the deltoid or gluteus muscles, into which a large volume of IG can be injected.^{51,56} If the IG is administered in the gluteus, the injection should be given in the superolateral aspect to avoid injury to the sciatic nerve.^{51,56}

Vaccine is recommended as postexposure prophylaxis in healthy persons 12 months through 40 years of age as of 2007, because it induces active immunity providing longer protection, has higher acceptability and availability, and is easy to administer.^{54,55,63,66,201}

IG does not interfere with the immune response to oral poliovirus vaccine, to yellow fever vaccine, or, in general, to inactivated vaccines. However, IG can interfere with the immune response to some live attenuated vaccines (e.g., measles-mumps-rubella vaccine [MMR] and varicella vaccine). Administration of MMR and varicella vaccines should be delayed for at least 3 months and at least 5 months, respectively, after the administration of immunoglobulin. Immunoglobulin should not be given within 2 weeks after the administration of MMR or within 3 weeks of the administration of varicella vaccine, unless the benefits of immunoglobulin administration are greater than the benefits of vaccination.^{51,56} For travelers younger than 1 year of age in whom the use of immunoglobulin may interfere with the administration of other needed vaccines (e.g., MMR and varicella), the use of inactivated hepatitis A vaccine could be considered (see the discussion on inactivated vaccines).

Serious adverse events from IG rarely occur. Because anaphylaxis has been reported after repeated administration to persons with IgA deficiency, these persons should not receive IG.¹²⁰ Pregnancy or lactation is not a contraindication to the administration of IG. For infants and pregnant women, a preparation that does not include thimerosal is preferable.

Hepatitis A Vaccine

The ability to propagate HAV in cell culture allowed the development of hepatitis A vaccines. Both inactivated and live attenuated hepatitis A vaccines have been developed by use of defined isolates from infected cell lines.^{106,239,240,255,303,344} Available data indicate that both inactivated and live attenuated hepatitis vaccine are capable of providing long-term protection, but only inactivated vaccines are licensed in the United States.^{232,286,176,403}

Vaccine Preparation and Performance

Inactivated hepatitis A vaccines are prepared by a method similar to that used to prepare inactivated poliovirus vaccine, by propagation of cell culture–adapted virus in human fibroblasts, purification by ultrafiltration or other methods, formalin inactivation, and adsorption to an aluminum hydroxide adjuvant.^{14,74} Inactivated vaccines using the HM175 strain (HAVRIX, GlaxoSmithKline) and the CR326F⁺ strain (VAQTA, Merck) have been licensed in pediatric and adult formulations for intramuscular administration and are available in the United States for persons 12 months of age and older (Table 168.1). One of these vaccines (HM175 strain) is formulated with 2-phenoxylethanol as a preservative, whereas the other is formulated without a preservative.²⁹⁰ The antigen content of one vaccine (CR326F⁺ strain) is expressed as units of HAV antigen as defined by a standard; the antigen content of the other vaccine

TABLE 168.1 Recommended Doses and Schedules for Inactivated Hepatitis A Vaccines Available in the United States

Age (y)	Vaccine ^a	Dose	Volume (mL)	No. of Doses	Schedule ^b (mo)
1–18	HAVRIX	720 ELU	0.5	2	0, 6–12
	VAQTA	25 U	0.5	2	0, 6–18
≥19	HAVRIX	1440 ELU	1.0	2	0, 6–12
	VAQTA	50 U	1.0	2	0, 6–18

ELU, Enzyme-linked immunosorbent assay units.
^aHAVRIX is manufactured from HAV strain HM175 by GlaxoSmithKline; VAQTA is manufactured from HAV strain CR326F⁺ by Merck & Co, Inc.; TWINRIX is a combined hepatitis A and hepatitis B vaccine that also contains 20 µg per dose recombinant hepatitis B surface antigen protein.
^bZero months indicates initial dose; subsequent numbers represent months after the initial dose.
^cAn alternative four-dose schedule, given on days 0, 7, 21–30, followed by a dose at month 12, also is licensed in the United States. This schedule is used prior to planned exposure with short notice.
From Centers for Disease Control and Prevention. Prevention of hepatitis A through active or passive immunization: recommendation from the advisory Committee on Immunization Practices (ACIP). *MMWR Morb Mortal Wkly Rep.* 2006;55(RR-7):1–23.

(HM175 strain) is determined by reactivity in a quantitative immunoassay for HAV antigen and is expressed as enzyme-linked immunosorbent assay units (ELU).

Two other inactivated hepatitis A vaccines are manufactured and available in Europe and other parts of the world.^{175,212,293,392} In addition, a combination inactivated hepatitis A and recombinant hepatitis B vaccine is available in the United States for persons 18 years and older,⁶¹ and a pediatric formulation is available in Europe, Canada, and other parts of the world.¹⁰⁷

In extensive studies in children and adults, the inactivated hepatitis A vaccines available in the United States have been found to be highly immunogenic. In general, after one dose of vaccine, 95% to 100% of children 1 year or older and adults respond with concentrations of antibody considered to be protective; a second dose given 6 to 18 months later results in a boost in antibody concentration and probably is important for long-term protection.^{20,25,74,169,251,271} Persons whose second dose is delayed as long as 3 to 8 years after the first dose have responses to vaccination similar to the responses of those who receive the vaccine on licensed schedules.^{24,179,413} Studies conducted among infants and children younger than 18 months have demonstrated that simultaneous administration of hepatitis A vaccine with diphtheria-tetanus-acellular pertussis (DTaP), *Haemophilus influenzae* type b, hepatitis B, MMR, and inactivated poliovirus vaccines does not affect the immunogenicity and reactogenicity of these vaccines.^{25,26,34,91,254,295,379} IgM anti-HAV occasionally can be detected by standard assays, primarily if it is measured soon (i.e., 2 to 3 weeks) after vaccination.^{341,390}

Conditions that may result in reduced immunogenicity include HIV infection, chronic liver disease, and older age. Among adults with HIV infection, 61% to 87% had protective antibody concentrations after completing the vaccination series.^{166,195,274,397} Higher CD4⁺ T-lymphocyte count at baseline was associated with response to vaccination.^{13,166,195,312,397} However, HIV-infected persons with normal or near-normal CD4⁺ T-lymphocyte counts have response rates that exceed 95%.⁴⁰¹ A retrospective study in adult patients with HIV who received two doses of HAV vaccine demonstrated a durable seropositive response for up to 6 to 10 years after HAV vaccination. Suppressed HIV RNA levels were associated with durable HAV responses.⁸⁹ Awareness of hepatitis susceptibility and hepatitis coinfection status in HIV-infected patients is essential for optimal clinical management. Despite recommendations for hepatitis screening and vaccination of HIV-infected MSM, rates for screening and vaccination remained suboptimal in the United States from 2004 to 2007.¹⁶⁸ HIV-infected patients have an elevated risk for HAV coinfection, which is significant considering the elevated prevalence of liver

disease in this population. Furthermore, HIV-infected persons may experience prolonged HAV viremia, which has important public health implications for transmission within the community.⁸⁹ Among persons with chronic liver disease, seroprotection rates were similar to those observed among healthy adults, but the final antibody concentrations were substantially lower.^{193,194,215,217}

Most infants born to anti-HAV-positive mothers have lost detectable antibody by the time they reach 12 to 15 months of age, and both pediatric hepatitis A vaccines are now licensed for use in children as young as 12 months.^{141,230,231} Studies in children younger than 1 year of age indicate that the vaccine is safe and immunogenic for those who do not have passively transferred antibody from previous maternal HAV infection.^{26,226,298,375} However, there are concerns that the presence of passively acquired maternal anti-HAV may substantially reduce hepatitis A vaccine immunogenicity. A study following 183 children over a 15-year period showed a 90% to 100% seropositivity at 10 years of age. However, there was a decrease through ages 15 to 16 years in children in whom vaccination began at age 6 months (50–75%) when compared to infants in whom vaccination began at 12 to 15 months of age.³⁵⁰ In studies of infants who received hepatitis A vaccine according to several different schedules, those with passively transferred maternal antibody at the time of vaccination responded, but final antibody concentrations were approximately one third to one tenth those of infants who did not have passively transferred antibody and were vaccinated according to the same schedule.^{26,92,226,228,298,375}

The clinical significance, if any, of these lower antibody concentrations is unknown. One study found that all infants vaccinated in the presence of passively transferred maternal antibody responded to a booster dose given 6 months later with an anamnestic response, suggesting that they had been primed by the primary series.⁹² However, in another small study, two of six children who had lost detectable antibody did not have an anamnestic response to a booster dose administered approximately 6 years after they had received the primary vaccine series in infancy in the presence of passively transferred antibody.^{135,136}

Inactivated hepatitis A vaccine has been shown to be highly efficacious in preventing clinically apparent disease. In a study of approximately 40,000 Thai children 1 to 16 years of age, the efficacy of inactivated vaccine (HM175 strain) was 94% (95% confidence interval [CI], 79%, 99%) after two doses (360 ELU per dose) administered 1 month apart.¹⁷⁶ In a study of another inactivated vaccine (CR326F strain) involving approximately 1000 children 2 to 16 years of age in a New York community with high hepatitis A rates, efficacy was 100% (lower bound of the 95% CI, 87%) starting 17 days after the administration of one dose (25 U).⁴⁰³

Since hepatitis A vaccines became available in the United States in 1995, studies, demonstration projects, and surveillance data have evaluated their effectiveness in controlling and preventing the development of hepatitis A in communities. In areas with the highest hepatitis A rates, such as Native American and Alaska Native communities, vaccination of the majority of children—and in some cases adolescents and young adults—resulted in a rapid decline in the incidence of disease, and with ongoing routine vaccination of children, the reduction in incidence of disease has been sustained.^{32,52,54,250} In larger, more heterogeneous communities with lower but consistently elevated hepatitis A rates, interruption of ongoing community-wide epidemics by vaccination of children proved more difficult.⁸⁶ In contrast, sustained routine vaccination of children can reduce hepatitis A incidence markedly during the course of time (see discussion on vaccine recommendations and use).^{16,91,112} Examination of time trends of hospitalization for hepatitis A at a tertiary pediatric hospital in Athens in 1999 to 2013 shows that hospitalization rates significantly decreased after implementation of the universal vaccination program in 2008 (from 50.5 to 20.8 per 1000 hospitalizations).^{287,288}

Hepatitis A vaccine also is effective when it is used to prevent infection after exposure. Hepatitis A vaccine administered soon after exposure prevented infection in a chimpanzee model.³¹⁴ Hepatitis A vaccine was found to be 79% efficacious in preventing infection in contrast to no treatment in a small randomized trial conducted in Italy.³²¹ In a randomized controlled trial conducted in Kazakhstan, among persons aged 2

to 40 years who were contacts of hepatitis A cases, the efficacy of hepatitis A vaccine administered within 14 days after exposure to HAV was shown to be similar to that of IG in healthy children and adults younger than 40 years of age.³⁹⁰ Based on their results and because the vaccine offers advantages over IG, the Advisory Committee on Immunization Practices (ACIP) of the US Public Health Service currently recommends the hepatitis A vaccine in preference to IG for postexposure prophylaxis of healthy persons from the ages of 12 months to 40 years.^{54,63} Advisory groups or expert panels in some other countries also have recommended that hepatitis A vaccine be used as the primary means of preventing hepatitis A after exposure.^{273,360}

Experience to date indicates that the incidence of adverse events after vaccination is comparable to that after the administration of other widely used vaccines. In prelicensure clinical studies in children, the side effects reported most frequently included soreness, tenderness, warmth, or induration at the injection site (4–19%); feeding problems (8%); and headache (4%).^{34,61,254} Through 2005, more than 188 million doses have been sold worldwide, including more than 50 million doses in the United States.⁶¹ No serious adverse events in children or adults have been identified that could be definitively ascribed to hepatitis A vaccine.^{35,61} The Vaccine Adverse Events Reporting System (maintained by the US Food and Drug Administration and the CDC) has received approximately 6000 reports of adverse events occurring after receipt of hepatitis A vaccine. The most common events were minor and of brief duration, such as fever, injection-site reactions, rash, and headache. The 871 serious adverse events included Guillain-Barré syndrome, elevated transaminases, idiopathic thrombocytopenic purpura, and seizures among children.^{61,276} Rare adverse events reported after marketing include syncope, jaundice, erythema multiforme, anaphylaxis, brachial plexus neuropathy, transverse myelitis, encephalopathy, and others. For events for which incidence rates are available, such as Guillain-Barré syndrome, reported rates were not higher than reported background rates.⁶¹

Anti-HAV persists at protective levels in vaccinated adults for at least 10 to 12 years after vaccination,^{381,385,384} and more recent publications have demonstrated protective levels up to 15 and 17 years after vaccination^{383,382} and in children for at least 5 to 10 years after vaccination.^{129,161,381} Available data indicate that both inactivated and live attenuated hepatitis A vaccine are capable of providing long-term protection for up to 15 years in both children and adults.²⁸⁶ Recent studies using mathematical models predict that 84% to 95% of children and adults who receive the hepatitis A vaccination would remain seropositive for 30 years.^{350,367}

In one follow-up study, two thirds of infants who did not have passively transferred maternal antibody at the time of vaccination had detectable anti-HAV 6 years later, and all who had lost antibody had an anamnestic response to a booster dose.^{135,136} Estimates based on kinetic models of decline in antibody suggest that the duration of protection could be 15 to 25 years or longer.^{381,411,412} A study randomized by maternal anti-HAV status included 197 children younger than 2 years of age who received different schedules of HAV vaccine and demonstrated that the seropositivity induced by hepatitis A vaccine can persist for at least 10 years regardless of presence of maternal anti-HAV.³³⁴

In some settings, performing prevaccination serologic testing may be considered in an attempt to reduce cost by not vaccinating persons with previous immunity.⁴⁷ Testing of children is not indicated because of their expected low prevalence of infection and the lower cost of vaccine for this age group. Testing may be considered for older adolescents and adults in certain population groups with a high prevalence of infection (e.g., Native Americans and Alaska Natives), persons who either were born in or lived for extensive periods in geographic areas that have high endemicity of HAV infection (e.g., Central and South America, Africa, and Asia), and adults 40 years of age and older. However, the cost of testing, the vaccine cost, and the likelihood that the person will return for vaccination should be taken into account. Postvaccination testing is not indicated because of the high rate of response to the vaccine. Furthermore, most anti-HAV testing methods licensed for use in the United States cannot reliably detect the low anti-HAV concentrations generated by immunization.^{55,66}

TABLE 168.2 Advisory Committee on Immunization Practices Recommendations for Routine Preexposure Use of Hepatitis A Vaccine

Group	Comments
All children at age 12–23 months ^a	Integrate into routine childhood vaccination schedule; children who are not vaccinated by age 2 years can be vaccinated at subsequent visits
Children age 2–18 years	Maintain existing program ^b ; can be considered in areas without existing programs
International travelers	Except persons traveling to Canada, Western Europe, Japan, Australia, or New Zealand, who are at no greater risk than in the United States Infants <12 months of age traveling to endemic area should receive immunoglobulin prophylaxis
Men who have sex with men	Includes adolescents
Illicit drug users	Includes adolescents
Persons with chronic liver disease	Increased risk of fulminant hepatitis A with HAV infection
Persons receiving clotting factor concentrates	
Persons who work with HAV in research settings	
Anyone wishing to obtain immunity	

HAV, Hepatitis A virus.

^aHepatitis A vaccine is not licensed for children younger than 12 months.

^bStates covered by 1999 ACIP recommendations (Alabama, Alaska, Arizona, California, Colorado, Idaho, Minnesota, Missouri, Nevada, New Mexico, Oklahoma, Oregon, South Dakota, Texas, Utah, Washington, Wyoming, and selected areas in other states).^{55,60}

From Centers for Disease Control and Prevention: Prevention of hepatitis A through active or passive immunization. Recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2006;55(RR-7):1–23.

Vaccine Recommendations and Use

Recommendations for the use of hepatitis A vaccine were issued first by the ACIP (Table 168.2), the American Academy of Pediatrics, and other groups in 1996 and updated in 1999 and 2006.^{8,51,55,59–61} As part of an incremental strategy aimed at achieving widespread routine vaccination, the 1999 recommendations called for routine vaccination of children living in areas where rates of hepatitis A consistently had been elevated. Various vaccination strategies that were suggested included vaccinating one or more single-age cohorts of children or adolescents, vaccinating children in selected settings (e.g., daycare), and vaccinating children and adolescents over a wide range of ages in a variety of settings, such as when they seek health care for other purposes. The final step in this incremental strategy, routine vaccination of children older than 12 months nationwide, was recommended by the ACIP in 2006.⁶¹

The impact of routine vaccination of children initially was shown in areas that historically have had the highest hepatitis A rates (e.g., Native American communities), where this strategy had been recommended since 1996. Surveys conducted in 1999 to 2000 indicated vaccination coverage of 50% to 80% of preschool- and school-age Native American and Alaska Native children, thus suggesting that the recommendation for routine vaccination was being implemented.³² By 2000, the incidence of hepatitis A in Native Americans and Alaska Natives had declined by 97% in contrast to the beginning of the preceding decade and was the same as the overall US rate.³²

National surveillance data indicate that routine vaccination of children living in areas with consistently elevated rates, which was recommended in 1999, has had an impact on the overall incidence of hepatitis A in

the United States. Rates declined most dramatically among children in parts of the country where routine vaccination of children was recommended and where the estimated coverage was highest.³⁹⁹

Since 2001, incidence rates in each successive year have been historic lows, with the 2010 rate of 0.54 cases per 100,000 population demonstrating a 94% decline in contrast to previous lows observed in the early 1990s.^{64,67}

Vaccine coverage data are limited but indicate that declines in incidence have occurred with modest levels of coverage, suggesting a strong herd immunity effect.^{9,94,105,322} Modeling studies suggested that 39% of potential cases were averted in 2001 because of the direct effects of immunization and herd immunity.³²² Similar observations have been made in Israel and Spain. The incidence of hepatitis A declined by 95% in Israel within 3 years after initiation of an immunization program among children 18 to 24 months old, even though no catch-up vaccination of other age groups was attempted.⁹² Routine vaccination of 12-year-old children in Catalonia, Spain, was followed by a 58% reduction in overall incidence.¹¹² Hepatitis A incidence is cyclic, and data from additional years are needed to verify that low rates are sustained and attributable to vaccination and to provide a definitive determination of the overall impact of this strategy of routine childhood vaccination. However, the consistency and strength of these data render alternative explanations unlikely.

Vaccination of successive cohorts of children eventually should result in a sustained reduction in the incidence of disease nationwide and thus provide the opportunity to eliminate HAV transmission. To achieve this goal, implementation of recent ACIP recommendations for vaccination of young children nationwide will be needed. Pediatric combination vaccines that include hepatitis A vaccine would facilitate this effort.

Vaccination of persons at increased risk for acquiring hepatitis A, including travelers to countries where hepatitis A is endemic, adolescent and adult MSM, persons who use illegal drugs, those who work with HAV in research settings, and persons who have clotting factor disorders, also is recommended.^{61,271,258} Persons with chronic liver disease who acquire hepatitis A have been reported to have a high case-fatality rate and are also recommended for vaccination.⁶¹

In 2009, ACIP recommended hepatitis A vaccination for all previously unvaccinated persons who anticipate close personal contact (e.g., household contact or regular babysitting) with an international adoptee from a country of high or intermediate endemicity during the first 60 days after arrival of the adoptee in the United States. The first dose of the two-dose hepatitis A vaccine series should be administered as soon as adoption is planned, ideally within 2 weeks before the arrival of the adoptee.^{63,65}

ACIP considered the likelihood that a child adopted by parents in the United States may be actively infected with hepatitis A and shedding virus at the time of the adoption. During 1998 to 2008, approximately 18,000 children were adopted from foreign countries by families in the United States each year. Of these, 99.8% came from countries where hepatitis A is considered of high or intermediate endemicity and approximately 85% were younger than 5 years.

ACIP also considered reports of HAV infection among persons in close contact with new adoptees from countries of high or intermediate endemicity. In 2007, the CDC was notified of a case of fulminant hepatitis A in a non-traveling household contact of an asymptomatic Ethiopian adoptee confirmed to have acute hepatitis A (IgM HAV positive). This case prompted an investigation that led to an identification of 20 additional cases of acute hepatitis A among persons who had close contact with newly arriving international adopted children and no history of traveling abroad.^{137,291,292} HAV infection in international adoptees and their contacts between 2007 and 2009 was also reported in Minnesota.³⁵⁶

HAV infection during pregnancy may be associated with a risk for gestational complications. HAV serology and vaccination for pregnant women should be considered in areas of high prevalence of acute hepatitis A.³¹⁹

Hepatitis A vaccination is not routinely recommended for health care personnel, persons attending or working in childcare centers, or persons who work in liquid or solid waste management (e.g., sewer workers or plumbers). ACIP does not recommend routine hepatitis A

vaccination for food service workers, but vaccination may be considered based on local epidemiology.^{55,66,335}
